## Table of Contents

List of Figures ..... VI
List of Tables ..... XI
Abstract ..... XIV
Introduction ..... XVI
Chapter I ..... 1
Introduction to Neural Networks ..... 1
I. 1 Advancements in Deep Learning ..... 1
I. 2 The Classification Problem ..... 2
I.2.2 Score Function: the Linear classification example ..... 3
I.2.3 Loss Function ..... 5
I. 3 Learning Parameters ..... 6
I.3.1 Optimization: Gradient Descent ..... 6
I.3.2 Mini-batch Gradient Descent and Stochastic Gradient Descent ..... 9
I.3.3 Backpropagation ..... 10
Interpretation of the gradient ..... 10
Compound expressions with the chain rule ..... 11
I. 4 A fundamental element: the neuron ..... 12
I.4.1 The neuron ..... 12
I.4.2 Neuron as linear classifier ..... 13
I.4.3 Commonly used activation functions ..... 14
Sigmoid ..... 14
Tanh ..... 15
ReLU ..... 15
I. 5 Artificial Neural Networks ..... 17
I.5.1 Layer organization in ANNs ..... 17
I.5.2 Sizing ANNs ..... 18
I.5.3 Data pre-processing ..... 19
Mean subtraction ..... 19
Normalization ..... 19
PCA and Whitening ..... 19
I. 6 Convolutional Neural Networks ..... 20
I.6.1 Architecture of a CNN ..... 21
Convolutional layer ..... 21
Pooling layer ..... 23
Normalization layer ..... 24
Fully-Connected layer ..... 24
I. 7 Binarized Neural Networks ..... 24
I.7.1 Binarization of weights ..... 26
I.7.2 Binarization of activations ..... 27
I.7.3 Bitwise operations ..... 28
I.7.4 Energy consumption in Binarized Neural Networks ..... 29
I.7.5 Accuracy of Binarized Neural Networks ..... 29
I.7.6 Hardware Implementation of Binarized Neural Networks ..... 30
FPGA implementation ..... 30
ASIC Implementation ..... 31
Chapter II ..... 33
II. 1 Definition and Applications ..... 33
II. 2 Sensors in Human Activity Recognition Systems ..... 34
II. 3 Classification Techniques ..... 35
II.3.1 Pattern Recognition methods ..... 35
Feature Extraction ..... 36
Classification ..... 36
II.3.2 Deep Learning methods ..... 36
II. 4 Time-Latency Requirements in Human Activity Recognition ..... 39
II. 5 Public Datasets for Human Activity Recognition ..... 40
II.5.1 PAMAP2 dataset ..... 40
II.5.2 SHL dataset ..... 40
II. 6 HW Solutions for Human Activity Recognition ..... 42
Chapter III ..... 45
III. 1 Device-Orientation problem ..... 45
III. 2 State-of-the-art solutions to the device-orientation problem ..... 46
III.2.1 Accelerometer + Magnetometer ..... 46
III.2.2 Accelerometer + Gyroscope ..... 47
III.2.3 Only Accelerometer ..... 48
III. 3 Proposed Solution ..... 49
III.3.1 Filtering Stage ..... 49
IIR Filters ..... 49
Structure Identification ..... 50
Coupled All-Pass filters ..... 51

## List of Figures

Figure I. 1 Graphical representation of the relation between Artificial Intelligence, Machine Learning, and Deep Learning .2 Figure I. 2 Example of a training dataset. In this dataset, 4 classes are considered: cat, dog, mug, hat. Each image in the dataset is labeled with one of the 4 classes .3
Figure I.3 Representation of the image space, where each image is a single point, and three classifiers are visualized. The cat classifier line shows all points in the space that get a score of zero for the cat class. The arrow shows the direction of increase, so all points to the left of the cat classifier line have positive (and linearly increasing) scores, and all points to the right have negative (and linearly decreasing) scores
.. 4
Figure I. 4 Graphical representation of the optimization process using Gradient Descent. The gradient of the loss function is computed at each step, and the parameters W are updated in the direction of the minimum. . .7
Figure I.5 Impact of the learning rate on the convergence of the optimization process. In (a) the learning rate is too small, and the minimum is not reached. In (b) the learning rate is too high, and the process does not converge 8

Figure I. 6 Example of a loss function with complex shape. Local minima and plateaus are the main issues: In the first case, the GD fails to reach the global minimum, as it gets trapped in a local minimum; in the second case, the gradient is very low and a large number of iterations are required to reach to effectively minimize the cost function. . 8
Figure I. 7 Graph of the computation for the function in (13) and of the backpropagation process. In the forward direction, the output value for the function is evaluated (values in black). In the backward direction, the backpropagation is performed, which starts at the end, and recursively applies the chain rule to compute the gradients (values in grey)12
Figure I. 8 Basic structure of a human neuron and its components ..... 13

Figure I.9Computational model of the neuron. The input signals of the neuron are denoted by xi, and each input is weighted by the synaptic strength wi. All the weighted inputs are summed up in the cell body, and an activation function, f , is applied.13

Figure I. 10 Sigmoid function...................................................................... 16
Figure I. 11 Tanh function............................................................................ 16
Figure I. 12 ReLU function........................................................................... 16
Figure I.13 Example of ANNs that use a stack of FC layers. (a) 2-layer NN with 3 inputs, and with one hidden layer of 4 neurons (or units) and one output layer with 2 neurons. (b) 3-layer NN with 3 inputs, and with two hidden layers of 4 neurons (or units) each and one output layer........... 17 Figure I. 14 Example of a binary classification problem. The black balls represent the first class, while the white balls represent the second class. The gray region is the decision region for the first class, otherwise, the second class is chosen. Considering a NN with one hidden layer, a better decision region can be obtained by increasing the number of neurons .18
Figure I. 15 Neurons in layers are arranged in three dimensions: depth, height, and width. Neurons are graphically represented by white circles, while each box represents the set of input activations for a layer. These correspond either to the output activations of the previous layer or to the input image for the first layer
Figure I.16 In the examples above, the white boxes represent the input activations, while the grey ones are the outputs. Thus, the input size $\mathrm{W}=5$, the receptive field $\mathrm{F}=3$, and the zero-padding $\mathrm{P}=1$. Two different cases are considered: on the left, the input stride $S=1$, thus the output size is equal to $(5+3+2) / 1+1=5$; on the right, the input stride $S=2$, thus the output size is equal to $(5+3+2) / 2+1=3$
Figure I.17 Example of MaxPool and AveragePool. In both cases the size of pooling is $2 \times 2$ and the stride is 2 . The size of the input volume ( $4 \times 4$ ) is scaled down by a factor of 2 , resulting in an output volume of size $2 \times 2 \ldots . . .24$ Figure III. 1 Graphical representation of the 2 possible reference frames for an inertial sensor. The Device Coordinate System is the reference frame defined by the device (solid line in the figure). The World Coordinate System is the reference frame defined by the world's gravity force (dotted line in the figure). In this figure, the World Coordinate System is defined as the reference frame whose z -axis is opposite to the gravity vector, g.......... 46 Figure III. 2 Coupled All-Pass realization of $G(z)$ and its power complementary function $\mathrm{H}(\mathrm{z}) . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . ~ 51 ~$

## Abstract

The research activity described in this thesis aims to demonstrate the possibility to embed Artificial Intelligence (AI) capabilities in wearable and portable devices by deploying and executing Neural Network (NN) models close to the sensing element. Among AI models, Deep Learning (DL) and Deep Neural Networks can achieve high performance in many tasks, e.g. image classification, activity recognition, and so on. However, DL models usually require a huge amount of memory resources and high-performance digital architecture to be executed. These specifications are hardly met by wearable and portable devices, which have to be as small as possible and guarantee a satisfactory battery lifetime. For this reason, the cloud computing strategy is often used. However, higher latencies occur in this case, which can be unacceptable in many latency-sensitive applications, such as autonomous vehicles or assisted microsurgery. Moreover, the data transfer consumes network bandwidth and energy. In this context, moving the computation close to the device is highly demanded, and it is named edgecomputing. However, deploying DL models on edge devices is still a challenge. General-purpose platforms (i.e. CPUs, GPUs) are not the best solution in terms of energy efficiency, especially for wearable and batterypowered devices, where the device lifetime is a major concern. Thus, a lot of research is being made about the design of custom HW accelerators for DL and to move the circuitry needed to implement the computation closer to the sensing element, thus obtaining a smart sensor. In this thesis, a novel Hybrid Binary Neural Network (HBN) model is proposed, which exploits the advantages of Binarized Neural Networks (BNNs). Human Activity Recognition (HAR) based on inertial sensors has been selected as a case study. Also, a pre-processing algorithm has been developed to solve the device-orientation problem for 3 -axis accelerometers. The pre-processing operations can improve the accuracy of the proposed system in some conditions when it is used in conjunction with the HBN model. The results show an accuracy of up to $99 \%$ in recognizing 5 human activities. After having developed the model, a custom ultra-low power HW accelerator has been designed and implemented with both FPGA and CMOS standard cells. Due to the very low operating frequency required by HAR applications,
power consumption has been reduced by reducing the number of resources. The design can implement both the pre-processing operation and the HBN model. The results show that the HW accelerator has a power consumption of $6.3 \mu \mathrm{~W}$ and an area occupation of 0.20 mm 2 when synthesized with CMOS 65 nm Low-Power (LP) High Voltage Threshold (HVT) standard cells. The proposed design has at least 7.3 times lower power consumption than the state-of-the-art solution. Also, a FPGA-based demo board has been developed to demonstrate the real-time operation of the system.

## Introduction

The research activity presented in this thesis aims to design an ultra-low power Hardware (HW) accelerator for Neural Networks (NNs) that can be embedded in wearable and portable devices. The objective is to demonstrate the possibility to integrate the HW accelerator into the sensor circuitry, in order to realize an ultra-low power Artificial Intelligence (AI)-based smart sensor.

Among AI techniques, Deep Learning (DL) is currently widely used thanks to its ability to reach very high performance in terms of accuracy, and it can outperform human performance in many tasks. Unfortunately, DL requires a huge amount of computations, which is far beyond the standard capabilities of modern portable or wearable devices. For this reason, cloud computing is often used because it offers scalable storage and processing services. In addition to scalability, the cloud provides easier maintainability than distributed Internet of Things (IoT) based solutions can offer. However, in many latency-sensitive applications, for example in autonomous vehicles or assisted microsurgery, the delay waiting for a result from a cloud-based AI is unacceptable. Moreover, sending a huge amount of data to the cloud for storage and processing might consume all network bandwidth making it a non-scalable and energy-hungry solution. Thus, moving the computation close to the device is highly demanded in many applications, and it is named edge-computing. However, deploying DL models on edge devices is still a challenge. General-purpose platforms (i.e. CPUs, GPUs) are not the best solution in terms of energy efficiency, especially for wearable and batterypowered devices, where the device lifetime is a major concern. Currently, a lot of research is being made about the design of custom energy-efficient HW accelerators for Deep Learning. Ultimately, great advantages can be gained in terms of reduced power consumption and area occupation by moving the circuitry needed to implement the computation closer to the sensing element, either on a single chip or on a System on Chip (SoC), thus obtaining a smart sensor.

In this regard, this research activity aims to design an ultra-low power smart sensor targeting $\mu \mathrm{W}$ power consumption. This is made possible by the use of a binarized version of a Convolutional Neural Network (CNN), which
is a CNN in which weights and the activations are binarized, i.e. constrained to +1 or -1 . Binarization enables the implementation of NN models on resource-constrained devices with lower power consumption and footprint. However, a major drawback of Binarized Neural Networks (BNN) is a significant decrease in accuracy compared to standard CNN models. As a solution, a new Hybrid Binary Neural Network (HBN) is proposed, where binarization has been carefully implemented to obtain a tradeoff between accuracy and required resources. Human Activity Recognition (HAR) is taken as a case study to test the proposed HBN model. More in detail, HAR based on inertial sensors, such as accelerometers and gyroscopes, has been considered. Also, a preprocessing algorithm has been developed, which allows extracting useful features from the raw data coming from a 3-axis accelerometer. Pre-processing operations allow compensating the accuracy loss in some conditions. The proposed HAR system is made up of a sensor, the pre-processing module, and the HNN. The sensor is a low-power digital 3-axis MEMS accelerometer, which can be used in conjunction with a 3-axis gyroscope. During pre-processing, raw data from the accelerometer are filtered to separate the high-frequency component from the low frequency/DC component, which roughly corresponds to the gravity acceleration. Then, a reference frame transformation is performed to represent the high-frequency component compared to a common reference system, to eliminate the dependence of the acquired data on the sensor orientation. Finally, classification is achieved through the HBN. The model has been constructed and tested in Lasagne, by implementing the binary layers with custom functions. The results show that the system reaches an accuracy of up to $99 \%$ in recognizing 5 different human activities.

After having developed the model, a custom ultra-low power HW accelerator has been designed and implemented with both FPGA and CMOS standard cells. Due to the very low operating frequency required by HAR applications, power consumption has been reduced by reducing the number of resources. The design can implement both the pre-processing operation and the HBN model. The results show that the HW accelerator has a power consumption of $6.3 \mu \mathrm{~W}$ and an area occupation of $0.20 \mathrm{~mm}^{2}$ when synthesized with CMOS 65 nm Low-Power (LP) High Voltage Threshold (HVT) standard cells. A FPGA-based demo board has been also realized to prove the real-time operation of the proposed HAR system.

The structure of the thesis is structured as follows.
Chapter I briefly introduces the theory behind NNs, describing how these models are built and trained. A focus is devoted to BNNs, which are the basis to understand the proposed HBN model. Also, state-of-the-art about HW implementations is provided.

Chapter II introduces HAR, which is the application field that has been used as a case study for the proposed system. An overview of algorithms and

HW solutions for HAR is provided, along with the description of two public datasets that have been used to test the proposed system.

Chapter III introduces the device-orientation problem in inertial sensors. State-of-the-art solutions are described based on the types of sensors that are involved. Then, a new solution is proposed to solve the device-orientation problem thanks to an HW-friendly algorithm.

Chapter IV introduces the proposed HBN model and describes how it is used to build the HAR system. The results from many tests on both two public datasets and a custom dataset are reported in terms of accuracy.

Chapter V describes the proposed HW accelerator. The results are reported for both the FPGA and CMOS standard cell implementations. Also, the FPGA-based demo board is briefly described.

## Chapter I Introduction to Neural Networks

## I. 1 Advancements in Deep Learning

Over the last few years, we have witnessed the huge spread of Deep Learning (DL) for a great variety of applications (LeCun, 2015), especially in image recognition (Krizhevsky, 2012), (Tompson, 2014), speech recognition (Hinton, 2012), (Nassif, 2019), autonomous driving (Li, 2019a) (Grigorescu, 2019), etc. As depicted in Figure I.1, DL is a subset of Machine Learning (ML), which in turn is a subset of Artificial Intelligence (AI). The term AI was first coined in 1956 by John McCarthy, who defines it as "the science and engineering of making intelligent machines" (McCharthy, 2007). This basically means the automated reproduction of human cognitive activities. Among the various AI techniques, ML allows the automated extraction of abstract knowledge from data and experience, which means ML algorithms can make predictions or decisions learning from data with which they are trained, without being explicitly programmed to do so. DL is a special case of ML, in which multi-layered representations are used to extract knowledge. The reason why DL has been so successful is that it allows overcoming a major issue of conventional ML techniques. Indeed, the latter are not able to extract useful information directly from raw data. Consequently, considerable domain-specific expertise is required to identify a suitable internal representation or a feature vector from which the knowledge can be effectively extracted. This process is usually called feature extraction. The great advantage of DL is the ability to avoid the feature extraction phase, thanks to its multi-layered structure, thus allowing extracting useful information from the raw data directly. However, there is a price to pay for this advantage. In fact, DL models have a huge computational complexity and require a large amount of memory to store all their parameters: as an example, the AlexNet (Krizhevsky, 2012) architecture requires approximately 837 M FLOPs to perform a single inference step, and 60 M parameters need to be stored. Thus, the execution of a DL model is usually unfeasible on CPUs or MCUs, and larger parallel-

## Chapter I

processing platforms, such as GPUs, must be used. Alternatively, DL can be delegated to the cloud, implementing the so-called cloud computing paradigm (Bianchi, 2019).

Figure I. 1 Graphical representation of the relation between Artificial Intelligence, Machine Learning, and Deep Learning.

## I. 2 The Classification Problem

One of the main tasks of DL models is classification, which is the task of assigning a label to input data from a fixed set of categories. A typical example is image classification: for example, an image classification model can take a single image and assigns a probability to 4 labels (cat, dog, hat, mug). This is a trivial task for a human to perform, but at the same time is a very complex problem to solve with conventional computer vision algorithms. In fact, it is not easy to come up with an algorithm for identifying cats in images, because each category should be carefully specified and described in the code. In doing so, so many aspects should be considered, such as viewpoint variation, scale variation, deformation, illumination conditions, etc. Therefore, a different approach must be used, which is referred to as the data-driven approach: many examples of each class are provided to the machine, and then, based on these examples, learning algorithms are developed that allows learning the features of all classes. The set of examples is almost always called training dataset. An example is shown in Figure I.2. Thus, the complete pipeline is the following:

1) Input construction: the input consists of a set of images (or a different kind of data for different tasks), each one is labeled with one of many different classes. This is the training dataset.
2) Learning: at this point, the objective is to use the training dataset to learn what every one of the classes looks like. This process is referred to as "training the classifier" or "learning a model".
3) Evaluation: in the end, the quality of the classifier is evaluated by asking it to predict labels for a new set of images, that is different
from the training dataset. The predicted labels are then compared with the true labels (ground truth).
The same concepts apply to other kinds of input data as well for example signals sampled by microphones or inertial sensors.

Figure I. 2 Example of a training dataset. In this dataset, 4 classes are considered: cat, dog, mug, hat. Each image in the dataset is labeled with one of the 4 classes.

## I.2.2 Score Function: the Linear classification example

To understand the meaning of the computational model of a neuron, linear classification must be introduced. To this aim, image classification is again used as an example. Let us assume a training dataset of images $x_{i} \in$ $R^{D}$, each one is associated with a label $y_{i}$. Here $i \in 1 \ldots N$ and $y_{i} \in 1 \ldots K$. That is, there are $N$ examples (each one with dimensionality $D$ ) and $K$ distinct categories. What we need is an approximation of the function that maps the raw image pixels to class scores. This is named score function, and it is defined as in (1).
$f: R^{D} \mapsto R^{K}$
The simplest possible function is the linear mapping:

$$
\begin{equation*}
f\left(x_{i}, W, b\right)=W x_{i}+b \tag{2}
\end{equation*}
$$

In (2), we are assuming that the image $x_{i}$ has all its pixels flattened out to a single column vector of shape $[D \times 1]$. The matrix $W$ and the vector $b$ are the parameters of the score function, and they have size respectively $[K \times D]$ and $[K \times 1]$. The parameters in $W$ are usually called weights, and $b$ is called the bias vector because it influences the outputs scores, but without interacting with the actual data $x_{i}$. Note that the single matrix multiplication

## Chapter I

$W x_{i}$ is effectively evaluating $K$ separate classifiers in parallel, where each classifier is a row of $W$. The goal is to set the parameters, $W$ and $B$, in such a way that the computed scores match the ground truth labels across the whole training set. Intuitively, we wish that the correct class has a score that is higher than the scores of the incorrect classes.

Since the images are stretched into high-dimensional column vectors, we can interpret each image as a single point in the space, i.e. each point is a point in $D$-dimensional space. If $D$ is very large, we cannot visualize the $D$ dimensional space. But if we imagine squashing all the dimensions into only two dimensions, then we can try to visualize what the classifier is doing. This is represented in Figure I.3. Each row of $W$ is a classifier for one of the classes. The geometric interpretation of these numbers is that as we change one of the rows of $W$, the corresponding line in the image-space will rotate in different directions. The biases $b$, on the other hand, allow our classifier to translate the lines. In fact, without the bias term, plugging $x_{i}=0$ would always give a score of zero regardless of the weights, so all lines would be forced to cross the origin.

Figure I. 3 Representation of the image space, where each image is a single point, and three classifiers are visualized. The cat classifier line shows all points in the space that get a score of zero for the cat class. The arrow shows the direction of increase, so all points to the left of the cat classifier line have positive (and linearly increasing) scores, and all points to the right have negative (and linearly decreasing) scores.

## I.2.3 Loss Function

Another important aspect of classification methods is the loss function. The loss function, sometimes also referred to as the cost function or the objective, measures how compatible a given set of parameters is, compared to the ground truth table in the training dataset. The loss will be high if we are doing a poor job of classifying the training data, and it will be low if we are doing well. Thus, the classification becomes an optimization problem in which we will minimize the loss function compared to parameters of the score function.

There are several ways to define the details of the loss function. A commonly used loss is the Multiclass Support Vector Machine (SVM) loss:

$$
\begin{equation*}
L_{i}=\sum_{i \neq y_{i}} \max \left(0, s_{j}-s_{y_{i}}+\Delta\right) \tag{3}
\end{equation*}
$$

where $s_{j}$ is the score for the $j$-th class, $s_{y i}$ is the score for the correct class, and $\Delta$ is a fixed margin. The function in (3) is often called hinge loss. Thus, the SVM loss is set up so that the correct class for each image has a score higher than the incorrect classed by some fixed margin $\Delta$. However, there is one problem that should be considered with the hinge loss: if a set of parameters $W$ allows classifying correctly all the examples (so the loss is zero for each example), then any multiple of these parameters $\lambda W$, where $\lambda>1$, will also give zero loss. In order to remove this ambiguity, a preference should be specified for a certain set of weights. A typical way to do so is to modify the loss by adding a regularization penalty $R(W)$. An example is the $L 2$ norm regularization, which gives preference to smaller weights by introducing an elementwise quadratic penalty over all the parameters:

$$
\begin{equation*}
R(W)=\sum_{k} \sum_{l} W_{k, l}^{2} \tag{4}
\end{equation*}
$$

Notice that the value of the regularization function in (4) does not depend on data, whereas it does depend on the weights. Thus, integrating the regularization term in (3), we obtain the complete SVM loss:

$$
\begin{equation*}
L=\frac{1}{N} \sum_{i} L_{i}+\lambda R(W) \tag{4}
\end{equation*}
$$

Two components can be identified: the data loss (which is the average loss over all examples) and the regularization loss. The parameter $\lambda$ does not result from the optimization process, and it must be arbitrarily defined and then tuned to obtain the best classification performance. These parameters are called hyperparameters.

Besides SVM, another very used classifier is Softmax. Different from SVM, the Softmax classifier gives a more intuitive meaning to the score assigned to each class. Indeed, a probabilistic interpretation is assigned to the

## Chapter I

output: while the function mapping in (2) stays unchanged, the hinge loss is replaced by the cross-entropy loss:
$L_{i}=-\log \left(\frac{e^{f_{y_{i}}}}{\sum_{j} e^{f_{j}}}\right)$
where $f_{j}$ is the $j$-th element of the vector of class scores $f$. Even in this case, the complete loss can be computed by applying (4). The function:
$S_{j}(z)=\frac{e^{z_{j}}}{\sum_{k} e^{z_{k}}}$
is the Softmax function. It takes a vector of real-valued scores and transforms it into a vector of values between 0 and 1 that sum to one. As a result, the expression in (6) can be interpreted as the probability that the $j$-th class is the correct one. Thus, ideally, we want the value of $S_{j}(z)$ to be close to 1 when $j$ is the correct class, while we want it to be close to 0 when $j$ is one of the wrong classes. In this way, the loss in (5) will be close to 0 if the probability associated with the correct class is high, while it will be higher otherwise.

## I. 3 Learning Parameters

After having defined the classifier and the loss function, an optimization method should be found to determine the set of weights $W$ for the classifier that minimizes the loss function. During the optimization process, the classifier is said to learn its parameters, therefore we usually talk about the learning process. Typically, in ML models, parameters are learned by feeding them with many examples, that is we train a certain model on a specific dataset. For this reason, the optimization process is also called the training process.

## I.3.1 Optimization: Gradient Descent

Finding the best set of weights $W$ might seem a very difficult or even impossible task, especially if we are trying to figure out the best configuration of weights for a whole DL model. However, the problem of identifying a set of weights $W$ that is slightly better is significantly less difficult. This basically means that the approach is to start with a random $W$ and then iteratively update it, making it better each time. On the basis of the above, making $W$ better means updating it in order to get a lower value when evaluating the loss function. An initial strategy might be to generate random perturbations $\delta W$ to $W$, and if the new loss is lower, then the update is performed. However, this is not the best solution. Indeed, the best direction along which $W$ should be changed can be computed, as it is mathematically
guaranteed to be the direction of the steepest descend. This direction will be related to the gradient of the loss function, which is a generalization of the slope for multiple variable functions. In practice, the gradient is a vector of slopes (more commonly referred to as derivatives) for each dimension in the input space. The mathematical expression for the derivative of a 1-D function compared to its input is:

$$
\begin{equation*}
\frac{d f(x)}{d x}=\lim _{h \rightarrow 0} \frac{f(x+h)-f(x)}{h} \tag{7}
\end{equation*}
$$

When the function takes a vector of numbers instead of a single number, the derivatives are called partial derivatives, and the gradient is the vector of partial derivatives in each dimension. The procedure of repeatedly evaluating the gradient and then performing a parameter updating is called Gradient Descent (GD). A graphical representation of this process is shown in Figure I.4. At the beginning of the process, $W$ is randomly set. Then the value of the cost function is decreased at each step by following the gradient.

An important parameter in GD is the size steps, determined by the learning rate hyperparameter. The effect of the learning rate on the optimization process is depicted in Figure I.5. If the learning rate is too small, then the optimization process will have to go through many iterations to converge, which will require a long time. On the other hand, if the learning rate is too high, the algorithm may diverge failing to find a good solution. Finally, not all functions have a regular trend, and this makes it more difficult to reach the minimum. In Figure I.6, two main challenges of GD are shown: if the random initialization starts the process on the left, then it will converge to a local minimum, which is not as good ad the global minimum; if it starts on the right, the gradient will be very low, and it will take a very long time to cross the plateau. Each iteration that leads to a parameter update is called epoch.

Figure I. 4 Graphical representation of the optimization process using Gradient Descent. The gradient of the loss function is computed at each step, and the parameters $W$ are updated in the direction of the minimum.

## Chapter I

Figure I. 5 Impact of the learning rate on the convergence of the optimization process. In (a) the learning rate is too small, and the minimum is not reached. In (b) the learning rate is too high, and the process does not converge.

Figure I. 6 Example of a loss function with complex shape. Local minima and plateaus are the main issues: In the first case, the GD fails to reach the global minimum, as it gets trapped in a local minimum; in the second case, the gradient is very low and a large number of iterations are required to reach to effectively minimize the cost function.

## I.3.2 Mini-batch Gradient Descent and Stochastic Gradient Descent

Notice that when using GD, the loss function must be evaluated on the whole training dataset before the parameters update happens. Nevertheless, in most applications, the training data can have millions of examples. Therefore, a huge amount of time would be required to compute the loss function for each update step. A very common approach is to compute the gradient over batches of the training data. This batch is then used to perform a parameter update. This method is called Mini-batch Gradient Descent (MGD). The reason this works well is that the examples in the training data are supposed to be correlated. Thus, the gradient from a mini-batch is a good approximation of the gradient of the full objective. In practice, much faster convergence can be achieved by evaluating the mini-batch gradients to perform more frequent parameter updates. The extreme case of this is Stochastic Gradient Descent (SGD), where the mini-batch contains only a single example. This is relatively less common because in practice it can be computationally much more efficient to evaluate the gradient for 100 examples, than the gradient for one example 100 times. Even though SGD technically refers to using a simple example at a time to evaluate the gradient, in most cases the term is used even when referring to MGD. The size of the mini-batch is a hyperparameter, and it is usually based on memory constraints. Typically, the size of the mini-batch is set to be a power of 2 because many vectorized operations work more efficiently when their inputs are sized in that way.

Due to their stochastic nature, MGD and SGD are much less regular than the standard GD algorithm. In particular, MGD is less regular than standard GD, and SGD is less regular than MGD. Thus, instead of gently decreasing until it reaches the minimum, the loss will experience some oscillations, decreasing only on average. Over time, it will end up being very close to the minimum, but once it gets there it will continue to oscillate around, never settling down. So, once the process stops, the final parameters are good, but not optimal. On the other hand, when the loss function is very irregular, this can help in jumping out of local minima, thus MGD and SGD have a better chance of finding the global minimum than standard GD does.

To summarize, the introduction of randomness helps in solving the local minima issue, but at the same, it avoids obtaining an optimal solution due to constant oscillations. One solution is to gradually reduce the learning rate: the steps are larger at the beginning of the optimization process (which helps make quick progress and escape local minima), then they get smaller and smaller, allowing the algorithm to settle at the global minimum. The function that determines the learning rate at each iteration is called the learning schedule. If the learning rate is reduced too quickly, the process may get stuck at a local minimum. If the learning rate is reduced too slowly, there

## Chapter I

may be oscillations around the global minimum for a long time, and the process may end up with a suboptimal solution if it is stopped too early.

## I.3.3 Backpropagation

Backpropagation is a way of computing gradients of expressions through the recursive application of chain rule. Thus, the problem consists of computing the gradient of a certain function $f(x)$, where $x$ is a vector of inputs. In the specific case of DL models, the function $f$ will correspond to the loss function, and the inputs $x$ will consist of the training data and the weights. Please notice that training data is given and fixed, whereas the weights are variables that must be optimized. Hence, during the optimization process, we usually compute the gradient for the parameters (e.g. $W, b$ ) so that we can use it to perform a parameter update.

## Interpretation of the gradient

To give an easy interpretation of the gradient, let us consider the elementary function:

$$
\begin{equation*}
f(x, y)=x y \quad \rightarrow \quad \frac{\partial f}{\partial x}=y \quad \frac{\partial f}{\partial y}=x \tag{8}
\end{equation*}
$$

It should be remembered that the derivatives indicate the rate of change of a function compared to a certain independent variable if this variable has an infinitesimal variation. The concept is expressed by (7). For example, if $x=4, y=-3$ then $f(x, y)=-12$. According to (8), the derivative on $x$ is equal to -3 . Thus, if the variable $x$ increased by a very tiny amount, the effect on $f$ would be a decrease by three times that amount. This can be seen by rewriting the equation in (7) as:

$$
\begin{equation*}
f(x+h)=f(x)+h \frac{d f(x)}{d x} \tag{9}
\end{equation*}
$$

As mentioned, the gradient of a function $f$ is the vector of partial derivatives. So, for the specific example that we are considering
$\nabla f=\left[\frac{\partial f}{\partial x}, \frac{\partial f}{\partial y}\right]=[y, x]$
For sake of completeness, the partial derivatives of other common basic inputs are reported below.

$$
\begin{equation*}
f(x, y)=x+y \quad \rightarrow \quad \frac{\partial f}{\partial x}=1 \quad \frac{\partial f}{\partial y}=1 \tag{11}
\end{equation*}
$$

$$
\begin{equation*}
f(x, y)=\max (x, y) \rightarrow \frac{\partial f}{\partial x}=1(x \geq y) \quad \frac{\partial f}{\partial y}=1(y \geq x) \tag{12}
\end{equation*}
$$

## Compound expressions with the chain rule

Based on (8), (11), and (12), the gradient of more complicated expressions that involve multiple composed functions can be computed. Let us consider the example:
$f(x, y, z)=(x+y) z$
The function in (13) is simple to differentiate directly, but a particular approach will be taken in the following to provide the idea behind backpropagation. More in details, the expression in (13) can be decomposed into two expressions:

$$
\begin{equation*}
q=x+y \quad f=q z \tag{14}
\end{equation*}
$$

The derivatives of both expressions in (14) can be computed by applying (8) and (11):
$\frac{\partial f}{\partial q}=z, \quad \frac{\partial f}{\partial z}=q, \quad \frac{\partial q}{\partial x}=1, \quad \frac{\partial q}{\partial y}=1$
However, the gradient on the intermediate value $q$ is not required. Instead, we are interested in the gradient of $f$ compared to $x, y$, and $z$. The chain rule states that the correct way to combine the gradient expressions in (15) is through multiplication, i.e.:

$$
\begin{equation*}
\frac{\partial f}{\partial x}=\frac{\partial f}{\partial q} \frac{\partial q}{\partial x} \tag{16}
\end{equation*}
$$

In practice, this is a simple multiplication of the two numbers that hold the two gradients. To clarify that, let us consider a simple example:

- Set the inputs: $x=-2 ; y=5 ; z=-4$;
- Perform the forward pass:

$$
\begin{aligned}
& q=x+y=3 \\
& f=q * z=-12
\end{aligned}
$$

- Backpropagation in reverse order:
- backpropagation through $f=q^{*} z$ :
gradient on $z=d f d z=q=3$
gradient on $q=d f d q=z=-4$
- backpropagation through $q=x+y$ :
$d f d x=d f d q * 1$ (the multiplication by 1 is the chain rule)
$d f d y=d f d q * 1$ (the multiplication by 1 is the chain rule)

## Chapter I

In the end, we obtained the gradients of $f$ compared to $x, y$, and $z$, which are respectively $d f d x, d f d y, d f d z$. The process above can be also represented with a graph, as shown in Figure I.7. The graph can be swiped both in the forward direction and in the backward direction. In the forward pass, the values from inputs to outputs are computed, while in the backward pass the backpropagation is performed by applying the chain rule as explained above.

Figure I. 7 Graph of the computation for the function in (13) and of the backpropagation process. In the forward direction, the output value for the function is evaluated (values in black). In the backward direction, the backpropagation is performed, which starts at the end, and recursively applies the chain rule to compute the gradients (values in grey).

## I. 4 A fundamental element: the neuron

One of the most used ML/DL models is the Artificial Neural Network (ANN), or simply Neural Network (NN). The idea behind ANNs is to mimic the behavior of the human brain.

## I.4.1 The neuron

The basic computational element of the brain is the neuron. Approximately 86 billion neurons can be found in the human nervous system and they are connected by approximately $10 \mathrm{E}+14-10 \mathrm{E}+15$ synapses. In Figure I.8, it is shown that each neuron receives input signals from its dendrites and produces output signals along its (single) axon. The axon eventually branches out and connects via synapses to the dendrites of other neurons. In Figure I. 9 the computational model of a neuron is depicted. The signals that travel along the axon (e.g. $x_{0}$ ) interact multiplicatively (e.g. wox $x_{0}$ ) with the dendrites of other neurons based on the synaptic strength at that synapse. (e.g. $w_{0}$ ). The dendrites carry the signals to the cell body where they all get summed. If the final sum is above a certain threshold, the neuron can fire, sending a spike along the axon. In the computational model, the frequency of the firing communicates information. Based on this rate-code
interpretation, the firing rate of the neuron is modeled with an activation function, $f$, which represents the frequency of the spikes along the axon. Historically, a common choice of function is the sigmoid function $\sigma$, since it takes a real-valued input (the strength after the sum) and squashes it to the range between 0 and 1. In summary, as reported in Figure I.9, each neuron performs a dot product with the input and its weights, adds the bias, and applies the activation function. Thus, the key arithmetic operation in neurons is the Multiply-Accumulate (MAC) operation.

Figure I. 8 Basic structure of a human neuron and its components.

Figure I. 9 Computational model of the neuron. The input signals of the neuron are denoted by $x_{i}$, and each input is weighted by the synaptic strength $w_{i}$. All the weighted inputs are summed up in the cell body, and an activation function, $f$, is applied.

## I.4.2 Neuron as linear classifier

The computational model of the neuron in Figure I. 9 might look familiar, as it reminds the equation of the linear classifier in (2). Thus, similarly to a linear classifier, a neuron can "like" or "dislike" certain linear regions of its output space. Hence, with an appropriate loss function on the neuron's

## Chapter I

output, the single neuron can become a linear classifier. For example, considering the sigmoid function as an activation function, the output of the neuron can be interpreted as a binary classifier. In particular, it can be seen as the probability:
$P\left(y_{i}=1 \mid x_{i} ; w\right)$
Since the probabilities of each class must sum to one, the probability of the other class will be
$P\left(y_{i}=0 \mid x_{i} ; w\right)=1-P\left(y_{i}=1 \mid x_{i} ; w\right)$
With this interpretation, the cross-entropy loss in (5) can be used during the optimization process. This is called binary Softmax classifier (also known as logistic regression). Since the sigmoid function is restricted to be in $(0,1)$, the predictions of this classifier are based on whether the output of the neuron is greater than 0.5 .

## I.4.3 Commonly used activation functions

An activation function (or non-linearity) takes a single value and executes a specific mathematical operation on it. In practice, several activation functions are used in DL models. Here below, the most common ones are shown.

## Sigmoid

The mathematical expression for the sigmoid is reported in (19) while the function is plotted in Figure I.10:
$\sigma(x)=\frac{1}{1+e^{-x}}$
The sigmoid function allows shrinking the range of representation for a certain number between 0 and 1. More precisely, large negative values become almost 0 , while large positive values become almost 1 . Although the sigmoid function is a good representation of the firing rate of a neuron (0 corresponding to a neuron that is not firing, and 1 corresponding to a neuron that is firing at the maximum frequency), it is almost ever used due to two major drawbacks:

- The sigmoid function tends to saturate, thus killing the gradient. In fact, when the neuron's activation saturates at either tail of 0 or 1, the gradient at these regions is almost zero. During backpropagation, the chain rule is applied, and this gradient must be multiplied by the gradient of the neuron's output. As a
consequence, when the local gradient is close to zero, no signal will be backpropagated through that neuron.
- The sigmoid outputs are not zero-centered. Again, this can be an issue during the backpropagation process. Indeed, if the input to a neuron is always positive (the sigmoid output is the input for other neurons), then the gradient on the weights $w$ in (2) will become either all positive or negative. This may introduce some undesirable zig-zagging effects in the gradient updates for the weights.

## Tanh

The mathematical expression for the tanh is reported in (20), where it is expressed in terms of the sigmoid function, while the function is plotted in Figure I.11.

$$
\begin{equation*}
\tanh (x)=2 \sigma(2 x)-1 \tag{20}
\end{equation*}
$$

The tanh non-linearity is very similar to the sigmoid, but it shrinks the range of representation of a number between -1 and +1 . It shares with the sigmoid the same issue about output saturation, but it has the advantage of being zero-centered. Therefore, in practice, the tanh non-linearity is always preferred to the sigmoid non-linearity.

## ReLU

The Rectified Linear Unit (ReLU) is currently one of the most used output activations. The function is plotted in Figure I.12, and it computes the function:

$$
\begin{equation*}
\operatorname{ReLU}(x)=\max (0, x) \tag{21}
\end{equation*}
$$

The function is basically a threshold at zero. Thanks to its linear form, the ReLU function has been found to greatly accelerate the convergence of SGD (or MGD) compared to sigmoid or tanh (Krizhevsky, 2012). Also, the ReLU can be implemented very easily, whereas both sigmoid and tanh require complex operations to be computed. However, there is an issue with the ReLU activation function: the gradient of ReLU is 0 when its input is lower than 0 . Thus, certain units can become "dead" because the backpropagated error is canceled whenever there is a negative input into the neuron.

## I. 5 Artificial Neural Networks

An ANN is built by connecting many neurons to each other. In particular, the output of some neurons is inputted to other neurons. In standard ANN, cycles are not allowed because that would result in an infinite loop during computation, especially during the forward pass.

Figure I. 13 Example of ANNs that use a stack of FC layers. (a) 2-layer $N N$ with 3 inputs, and with one hidden layer of 4 neurons (or units) and one output layer with 2 neurons. (b) 3-layer NN with 3 inputs, and with two hidden layers of 4 neurons (or units) each and one output layer.

## I.5.1 Layer organization in ANNs

An important thing to notice is that neurons are not chaotically connected to each other. On the contrary, ANNs are organized structures where neurons are collected in layers. Different types of layers exist, however, let us take the example of Fully Connected (FC) layers to clarify the concept. FC layer is by far one of the most used layers. As its name suggests, all neurons in a FC layer are connected to every output from the previous layer, while neurons within the layer share no connections. Two examples of ANNs that use a stack of FC layers are shown in Figure I.13. We must distinguish between 3 types of layers:

- Input layer: it is the first layer of a NN , and corresponds to the input.
- Output layer: it is the last layer of a NN. Unlike all other layers, here it is common that neurons do not have an activation function. This is because the output layer is usually taken to represent the class scores in classification or a real-valued target in regression.
- Hidden layers: they are all the layers between the input layer and the output layer.

## Chapter I

Notice that an $N$-layer NN is a NN with $N$ layers, but in $N$ the input layer is not counted. Thus, in Figure I.13a a 2-layer NN is represented, while in Figure I.13b a 3-layer NN is represented. A particular case is the single-layer NN , in which no hidden layers exist, and the input is directly mapped to the output. ANN like the ones in Figure I. 13 (all layers are FC layers) are sometimes called Multi-Layer Perceptrons (MLPs).

Figure I. 14 Example of a binary classification problem. The black balls represent the first class, while the white balls represent the second class. The gray region is the decision region for the first class, otherwise, the second class is chosen. Considering a NN with one hidden layer, a better decision region can be obtained by increasing the number of neurons.

## I.5.2 Sizing ANNs

Mainly two metrics can be used to measure the size of a NN : the number of neurons, or more commonly the number of parameters. The latter allows getting an insight into the amount of memory required to store all parameters. Considering Figure I.13, the two metrics can be computed as follow:

- In Figure I.13a, the NN has $4+2=6$ neurons (inputs must not be counted); the number of parameters is $(3 \times 4)+(4 \times 2)=20$ weights and $4+2=6$ biases, for a total of 26 learnable parameters.
- In Figure I.13b, the NN has $4+4+1=9$ neurons; the number of parameters is $(3 \times 4)+(4 \times 4)+(4 \times 1)=32$ and $4+4+1=9$ biases, for a total of 41 learnable parameters.
Modern NNs have more than 100 million parameters and are usually made up of 10-20 layers, from which the name DL. In fact, a famous theorem formulated by Cybenco in 1989 (Cybenco, 1989) states that a NN with at least one hidden layer is a universal approximator, that is the NN can approximate any continuous function. The problem of this theorem is that nothing is said about the number of neurons required in the hidden layer to get a good approximation. In practice, it turns out that deeper networks (with more hidden layers) can perform much better than NN with a single hidden
layer. At this point, it is crucial to understand how to know the number of hidden layers to use and, also, how large each layer should be. To this aim, it is useful to introduce the concept of capacity of a NN. The capacity is related to the space of representable functions. In general, the capacity of NN increases as the size and the number of layers increases. The idea is that more neurons can better cooperate to express much more different functions. This is illustrated in Figure I.14. However, attention must be paid because it is easier to overfit the training data when the capacity of the NN is high. Overfitting occurs when a NN with high capacity learns noise in the data instead of the abstract relationship. Fortunately, there are many ways to prevent overfitting, such as L2 regularization, dropout (Srivastava, 2014), etc. In practice, it is always better to use these methods to control overfitting instead of reducing the size of the NN .

## I.5.3 Data pre-processing

In most cases, ANNs are not fed with raw data, and some kind of data pre-processing is performed. Here below, 3 common forms of datapreprocessing are briefly described.

## Mean subtraction

Mean subtraction consists of subtracting the mean computed across every feature in the data and has the geometric interpretation of centering the data around the origin along each dimension.

## Normalization

Normalization is a pre-processing technique used to make all samples from input data approximately the same order of magnitude. This can be achieved in two ways. A solution is to divide each dimension by its standard deviation, whereas the other one is to normalize all values in the range $[-1,1]$, where -1 represents the minimum value, and +1 represents the maximum value.

## PCA and Whitening

In this kind of pre-processing, first, a mean subtraction is performed as described above. Then, the covariance matrix is computed which gives information about the correlation between dimensions of the data. The two operations are described in (22) and (23) respectively, where $X_{i}$ is the $i$-th input tensor with $N$ elements, and $C$ is the covariance matrix.
$\bar{X}=\sum_{i=1}^{D} X_{i}$

Chapter I
$C=\left(\bar{X}^{T} \cdot X\right) / N$
At this point, the Single Value Decomposition (SVD) factorization of the covariance matrix can be performed, which gives the eigenvectors and the singular values of $C$. It should be noted that the eigenvectors constitute a set of orthonormal vectors, thus they can be considered as basis vectors. Thus, the zero-centered data obtained with (22) is projected on the eigenvectors to decorrelate the data. This pre-processing is named Principal Component Analysis (PCA) reduction. It allows reducing the number of dimensions $D$ of input data. While zero-centering and normalization are commonly used also in DL models, PCA is mostly used in single layer ANN or standard Pattern Recognition (PR) methods (Abdi, 2010).

## I. 6 Convolutional Neural Networks

Convolutional Neural Networks (CNNs) are historically related to image recognition because they introduce many advantages when elaborating images. Despite this, they are successfully used for other purposes as well, especially times series classification (Zhao, 2017). CNNs, are very similar to ANNs: they are made up of neurons, and they have learnable weights and biases. The neuron retains the same structure as explained in paragraph I.4, and the whole network still expresses a differentiable score function. What actually changes is the way neurons are connected between consecutive layers.

As explained in paragraph I.5, ANNs receive an input in the form of a single vector and elaborate it through a series of hidden layers. Each neuron in each hidden layer of the network is fully connected to all neurons of the previous layer. To understand the limitations of this type of organization, let us take the CIFAR-10 dataset (Krizhevsky, 2009) as an example. The CIFAR-10 dataset consists of $6000032 \times 32$ color images in 10 classes, with 6000 images per class. Thus, the size of each input image is $32 \times 32 \times 3$, and each neuron in the first hidden layer of a given ANN would have $32 \cdot 32 \cdot 3=3072$ weights. If we imagine that each weight is represented using a 32-bit Floating-Point (FP) (IEEE, 2019) coding, 12 KB would be required just to store the weights of each neuron in the first hidden layer. Moreover, many hidden layers are usually needed, and hundreds or also thousands of neurons are present in practice in each hidden layer. In this context, the number of total parameters becomes incredibly high, and with it the memory requirement. In addition to that, a so high number of parameters quite often leads to overfitting. Thus, the full connectivity is wasteful and must be replaced by a different kind of organization.

## I.6.1 Architecture of a CNN

CNNs allow overcoming the issues introduced by full connectivity. As said before, CNNs are historically related to image processing. In fact, the core idea in CNNs is to replace the set of weights in a certain layer with a set of filters. Thus, the output of the layer is computed by filtering its input. However, differently from standard signal-processing techniques, the filter parameters are not hand-crafted, whereas they are the result of the learning process. Another difference with regular ANNs is that CNNs have neurons arranged in 3 dimensions: width, height, depth. This is represented in Figure I.15. For example, the input images in CIFAR-10 are an input volume of dimensions $32 \times 32 \times 3$ (width, height, depth, respectively). Every layer in CNNs transforms a 3 D input volume to a 3 D output volume of neuron activations. A simple CNN is a sequence of layers.

Figure I. 15 Neurons in layers are arranged in three dimensions: depth, height, and width. Neurons are graphically represented by white circles, while each box represents the set of input activations for a layer. These correspond either to the output activations of the previous layer or to the input image for the first layer.

A CNN is a sequence of layers. The three main types of layers used to build these networks are Convolutional layers (CONV), Pooling layers, and Fully-Connected layers (FC). The latter type of layer is exactly the same as seen in regular ANN.

## Convolutional layer

The CONV layer is the main component of a CNN. The parameters of a CONV layer consist of a set of learnable filters. Every filter has a small size along width and height but extends to the full depth of the input volume. If we keep considering the image processing as an example, a typical filter on the first layer of a CNN might have size $5 \times 5 \times 3$, i.e. 5 pixels width and

## Chapter I

height, and 3 because images have depth 3 (the color channels). During the forward pass, each filter slides across the width and height of the input activations and compute dot products between the weights of the filter and the input. At the end of this process, a 2-dimensional activation map (or feature map) is obtained, which is the result of applying that filter to the full input volume. In a CONV layer, many filters are applied to the input, and each of them will produce a different feature map. All feature maps are concatenated along the depth dimension, thus constituting the output of the layer.

This way of computing a CONV layer may be expressed in terms of neurons as well. To do that, we must imagine that each neuron of a layer is connected to only a local region of the input volume. The size of this region is a hyperparameter called the receptive field of the neuron, which corresponds to the filter size. It should be noticed that the size of the receptive field along the depth dimension is always equal to the depth of the input volume. However, the receptive field alone is not enough to define the size of the output volume. To this aim, three hyperparameters must be defined: depth, stride, and zero-padding:

- The depth of the output volume corresponds to the number of filters that are associated with the given layer.
- The stride defines the step with which the filter slides across the input. When the stride is 1 , then the filters shift one position at a time. When the stride is 2 then the filters shift of 2 positions at a time, thus skipping one activation. This will produce an output activation map smaller than the input one.
- In some cases, it may be useful to pad the input activation map with zeros around the border. The size of zero-padding is a hyperparameter, which can be used to control the size of the output activation map. In most cases, zero-padding is used to preserve the size of input along the width and height dimensions.

Figure I. 16 In the examples above, the white boxes represent the input activations, while the grey ones are the outputs. Thus, the input size $W=5$, the receptive field $F=3$, and the zero-padding $P=1$. Two different cases are considered: on the left, the input stride $S=1$, thus the output size is equal to $(5+3+2) / 1+1=5$; on the right, the input stride $S=2$, thus the output size is equal to $(5+3+2) / 2+1=3$.

Based on what said above, the spatial size of the output feature map (i.e. width $\times$ height) can be computed as follow:

$$
\begin{equation*}
O=(W-F+2 P) / S+1 \tag{24}
\end{equation*}
$$

where $O$ is the size of the output feature map, $W$ is the size of the input feature map, $F$ is the receptive field of the CONV layer, $S$ is the stride with which filters are applied, and $P$ is the amount of zero-padding. The equation in (24) holds both for 2D square filters and 1D filters. An example is shown in Figure I.16. Looking at the example on the left, it can be noticed that the input size and the output size are equal: also 5. In general, when the stride is 1 , setting zero-padding to:
$P=(F-1) / 2$
ensures that the input activation map and the output activation map will have the same size.

Local connectivity is not the only feature of neurons in CONV layers. Indeed, parameter sharing is also used to control the number of weights. This is based on the concept that if some weights are useful to compute the output activation from some position $\left(x_{1}, y_{1}\right)$, then it should also be useful to compute the output activation at a different position $\left(x_{2}, y_{2}\right)$. Thus, each neuron in a single 2-dimensional slice of depth, namely a depth slice, is constrained to use the same weights. For example, if the input volume has a size $32 \times 32 \times 3$, all neurons in each depth slice of size $32 \times 32$ will use the same weights. Therefore, only 3 unique sets of weights (one for each depth slice) are required. Notice that if all neurons in a single depth slice are using the same weight vector, then the forward pass of the CONV layer can be computed as a convolution of the weights with the input volume. Hence the name Convolutional Layer. For this reason, the set of weights are generally referred to as filters or kernels.

## Pooling layer

Another commonly used layer in CNN is the Pooling layer, which is used to progressively reduce the spatial size of the feature maps. This layer is used to reduce the amount of memory and computational power required by the model. Consequently, it also helps in preventing overfitting. The Pooling layer operates independently on every depth slice in the input and resizes it spatially. The most common forms of pooling are max-pooling (MaxPool) and average-pooling (AveragePool), which perform the max and average operations respectively with a particular filter size. The most common form is MaxPool with filter size 2 (or $2 \times 2$ ) with a stride 2, which corresponds to down-sampling the input volume by 2. An example is given in Figure I.17.

Chapter I

Figure I. 17 Example of MaxPool and AveragePool. In both cases the size of pooling is $2 \times 2$ and the stride is 2 . The size of the input volume ( $4 \times 4$ ) is scaled down by a factor of 2 , resulting in an output volume of size $2 \times 2$.

## Normalization layer

Many types of normalization layers exist for use in CNNs. One of the most useful ones is the Batch Normalization (BatchNorm) layer (Ioffe, 2015). This normalization layer aims to standardize the inputs to a layer for each mini-batch. In fact, the distribution of the inputs to layers may change after each mini-batch, thus making it hard to properly accomplish the training process. In particular, BatchNorm performs a rescaling of data to have a mean of zero and a standard deviation of one, i.e. a standard Gaussian. This has the effect of stabilizing and speeding up the training process.

## Fully-Connected layer

In a FC layer, all neurons of a certain layer are connected to the neurons of the previous layer. This is the layer described for regular ANNs in paragraph I.5. Differently from CONV layers, neurons in FC layers are not arranged along 3 dimensions. As a consequence, when a FC layer receives input from a CONV layer, the 3 -dimensional feature map needs to be flattened into a vector of input activations.

## I. 7 Binarized Neural Networks

The main issue of NNs, especially Deep Neural Networks (DNNs), is that they require a huge amount of memory to store parameters and computational power. For example, AlexNet (Krizhevsky, 2012) and ResNet (He, 2016) require 200 MB of memory, VGG-Net (Simonyan, 2014) requires 500 MB of memory. It is clear that it is hard to deploy those models on portable and wearable devices, which are constrained both in terms of resources and power consumption. Currently, quantization is the most appealing solution to this problem. The core idea in Quantized Neural

Networks (QNNs) is to reduce the number of bits used to represent values in the model. In fact, 32-bit Floating-Point (FP) values are generally used to compute neural network models. Quantization techniques aim to execute the model by using a lower number of bits and representing values with a FixedPoint (FI) coding. The lower number of bits allows reducing the amount of memory required to store parameters (i.e., a $4 \times$ memory saving is obtained by switching from 32-bit FP to 8 -bit FI), whereas using FI rather than FP is beneficial in terms of hardware complexity. Indeed, FP arithmetic circuits are generally larger and consume more power than the FI counterpart. The advantage in terms of area and energy consumption is clear if considering the values in Table I.1. The energy consumption decreases with the number of bits of the arithmetic operators, and FP circuits are more consuming than the FI counterpart. But more importantly, memory accesses typically consume more than arithmetic operations, and the cost of memory accesses increases with memory size.

The price to pay for the reduction of the memory requirements and the computational power is generally a decrease in the accuracy of the model. Thus, QNNs need to be careful designed in order to preserve as much as possible the original accuracy.

Table I.1 Energy consumption and Area occupation for different arithmetic operations and memory accesses. Energy values are from Horowitz (2014). Area values come from synthesis with TSMC 45 nm standard cells.

| Operation | Energy (pJ) | Area $\left(\mu \mathrm{m}^{2}\right)$ |
| :---: | :---: | :---: |
| 8b Add | 0.03 | 36 |
| 16b Add | 0.05 | 67 |
| 32b Add | 0.1 | 137 |
| 16b FP Add | 0.4 | 1360 |
| 32b FP Add | 0.9 | 4184 |
| 8b Mult | 0.2 | 282 |
| 32b Mult | 3.1 | 3495 |
| 16b FP Mult | 1.1 | 1640 |
| 32b FP Mult | 3.7 | 7700 |
| 32b SRAM Read (8 KB) | 5 | N.A. |
| 32b DRAM Read (Off-chip) | 640 | N.A. |

The extreme case of quantization is binarization. Binarization is a 1-bit quantization, that is values can only have two possible values. Generally, -1 and +1 are used. NNs that exploit binarization are referred to as Binarized Neural Networks (BNNs). One critical aspect is that backpropagation cannot be directly applied to BNNs, since it is not possible to update weights in small increments. The simplest workaround is to train the NN model with 32-bit FP values and then quantize the resulting weights and biases. This

## Chapter I

approach is usually named post-training quantization. Unfortunately, the highest degradation of accuracy is obtained with this method (Finkelstein, 2019).

## I.7.1 Binarization of weights

Courbariaux et al. (2015), for the first time, provided a way to train NNs using binary weights, which is named BinaryConnect. It should be noticed that many MAC operations are replaced by simple Additions/Subtractions (ADD/SUB) operations when using binary weights. This is a huge advantage, as FI adders are much less expensive both in terms of area and energy than FI MAC circuits (David, 2007). Using binary values during training provides a more representative loss to train against post-training quantization. The binarization operation transforms the real-valued weights into two possible values. A very straightforward binarization operation is based on the sign function:

$$
w_{b}=\left\{\begin{array}{cc}
+1 & \text { if } w \geq 0  \tag{26}\\
-1 & \text { otherwise }
\end{array}\right.
$$

where $w_{b}$ is the binarized and $w$ the real-valued weight. Although this is a deterministic operation, averaging this discretization over the many input weights of a hidden unit could compensate for the loss of information. An alternative that allows having a finer and more correct averaging process is to binarize stochastically:

$$
w_{b}= \begin{cases}+1 & \text { with probability } p=\sigma(w)  \tag{27}\\ -1 & \text { with probability } 1-p\end{cases}
$$

where $\sigma$ is the hard sigmoid function:

$$
\begin{equation*}
\sigma(x)=\operatorname{clip}\left(\frac{x+1}{2}, 0,1\right)=\max \left(0, \min \left(1, \frac{x+1}{2}\right)\right) \tag{28}
\end{equation*}
$$

The reason why hard sigmoid is used is that it is far less computationally expensive than the original version in (19).

The key point in BinaryConnect (Courbariaux, 2015) is that weights are binarized during the forward and backward propagations but not during parameter updates. In fact, keeping good precision during updates is necessary for SGD to work, because a large number of almost infinitesimal changes in the direction that most minimize the loss function must be performed. The core idea is that what matters most at the end of training is the sign of the weights, but before that, a lot of small changes to a continuous-valued quantity are performed, and only at the end its sign is considered. In more detail, at training time, BinaryConnect randomly picks a
binary value $(+1$ or -1$)$ for each weight, for each mini-batch, for both the forward and the backward steps. However, the update is accumulated in a real-valued variable storing the parameter. Since the binarization is not influenced by variations of the real-valued weights when its magnitude is above the range $[-1,1]$, the real-valued weights are clipped within the $[-1,1]$ interval right after the weight updates. The real-valued weights would otherwise grow very large without any impact on the binary weights.

One thing to notice is that the derivative of the sign function in (26) is zero almost everywhere, which seems to be incompatible with the backpropagation algorithm. This is true even if stochastic quantization in (27) is used. A solution to this problem was proposed in the paper by Bengio et al. (2013), where the straight-through estimator (STE) is used to estimate the gradient through stochastic neurons. The idea is simply to backpropagate through the sign function as if it had been the identity function.

## I.7.2 Binarization of activations

Thanks to the binarization of weights, a large amount of memory can be saved compared to a FP-32 NN model. Also, binarizations allow replacing MAC operations with simpler ADD/SUB operations. However, a further advantage can be gained by binarizing activations as well. In doing so, an additional amount of memory is saved (i.e. buffers to store activations can be smaller) and bit-wise operations can further reduce the computational complexity, and hence the power consumption, of the model.

Binarization of the activations in BNNs was introduced for the first time by Courbariaux et al. (2016). In order to binarize the activations, they are passed through a sign function using a STE in the backward step, similar to what happens in the binarization of weights. The sign function is used as the activation function in the NN model. A version of the STE that considers the clipping effect is applied to the deterministic sign function in (26). In particular, it was observed that to obtain good results, the gradient must be canceled out if the input to the activation function is too large. Thus, considering the activation function, i.e. the sign function:
$q=\operatorname{sign}(r)$
the STE of the gradient of the cost function $C$ compared to $r$ is computed as:

$$
\begin{equation*}
\frac{\partial C}{\partial r}=g_{r}=g_{q} 1_{|r| \leq 1} \tag{30}
\end{equation*}
$$

where:

Chapter I

$$
1_{|r| \leq 1}=\left\{\begin{array}{lc}
1 & \text { when }|r| \leq 1  \tag{31}\\
0 & \text { otherwise }
\end{array}\right.
$$

## I.7.3 Bitwise operations

When using binary values, the dot product between weights and activations can be reduced to bitwise operations. The binary values can be either +1 or -1 , which are encoded with 1 and 0 , respectively. Using an XNOR logical operation at bit level is equivalent to perform multiplication on the binary values. This is shown in Table I.2.

Table I.2 Equivalence between XNOR logical operation between Bitl and Bit2 and multiply operation between Value1 and Value2.

| Bit1 (Value1) | Bit2 (Value2) | XNOR (Multiply) |
| :---: | :---: | :---: |
| $0(-1)$ | $0(-1)$ | $1(+1)$ |
| $0(-1)$ | $1(+1)$ | $0(-1)$ |
| $1(+1)$ | $0(-1)$ | $0(-1)$ |
| $1(+1)$ | $1(+1)$ | $1(+1)$ |

Thus, the XNOR function can be used to perform multiply operations between binary values. However, dot product operation also requires the accumulation of the results from the element-wise multiplication between elements of the input vectors. It turns out that the accumulation operation can be performed through the popcount operation, which is the process of counting the number of 1 s in a binary value. More in detail, the accumulation can be performed by counting the number of 1 s in a group of XNOR products, multiplying this value by 2 , and subtracting the total number of bits producing an integer value. The reason why this holds is given below. Let us consider the accumulation of $N$ binary values. The relation between the bit representation $x_{b}$ (i.e., 0 and 1) and the integer values $x$ (i.e., -1 and +1 ) is the following:
$x=2 x_{b}-1$
When the accumulation of $N$ binary values is performed, the result is:
$\sum_{i=1}^{N} x_{i}=2 \sum_{i=1}^{N}\left(x_{b}\right)_{i}-N$

## I.7.4 Energy consumption in Binarized Neural Networks

BNNs can drastically reduce memory size and accesses, and replace most arithmetic operations with bitwise operations. In comparison with 32-bit FP NNs, BNNs require 32 times smaller memory size and 32 times fewer memory accesses, with relevant advantages in energy consumption according to Table I.1. Moreover, considering that the key arithmetic operation in NNs is the MAC operation, 32-bit FP MAC operations are replaced by 1-bit XNOR-popcount operations. This can lead to faster execution times and fewer hardware resources required in digital design architectures, especially for specialized ones (Simons, 2019). Despite this, it should be pointed out that training a BNN takes longer than traditional NNs due to the STE heuristic needed to approximate the gradient of the realvalued weights.

## I.7.5 Accuracy of Binarized Neural Networks

While BNNs are compact and efficient compared to their full precision counterparts, they suffer from degradation of accuracy. A summary of the state of the art in terms of accuracy is reported in Table I.3. Results refer to classification performance on the ImageNet dataset (Deng, 2009). Looking at the values in the table, it turns out that a minimum accuracy loss of about 3 percentage points must be accepted when using binary weights. The accuracy loss is even higher when binarizing both weights and activation, where the minimum accuracy loss is about 20 percentage points.

Table I. 3 Comparison of accuracy on the ImageNet dataset (Deng, 2009) between 32-bit FP model and BNNs. For each topology, the bit-width is expressed as $W / A$, that is weights/activations. Where binarization occurs, the accuracy loss compared to the FP model is reported.

| Topology | Bit-width <br> (W/A) | Top-1 accuracy | Accuracy <br> Loss | Source |
| :---: | :---: | :---: | :---: | :---: |
| AlexNet | $32 / 32$ | $57.1 \%$ | - | (Zhang, 2018) |
| AlexNet | $1 / 32$ | $35.4 \%$ | $-21.7 \%$ | (Courbariaux, 2015) |
| AlexNet | $1 / 1$ | $27.9 \%$ | $-29.2 \%$ | (Hubara, 2016)] |
| ResNet-18 | $32 / 32$ | $69.6 \%$ | - | (Zhang, 2018) |
| ResNet-18 | $1 / 32$ | $60.8 \%$ | $-8.8 \%$ | (Rastegari, 2016) |
| ResNet-18 | $1 / 1$ | $42.7 \%$ | $-26.9 \%$ | (Lin, 2017) |
| ResNet-34 | $32 / 32$ | $73.3 \%$ | - | (Zhang, 2018) |
| ResNet-34 | $1 / 32$ | $70.4 \%$ | $-2.9 \%$ | (Qin, 2020) |
| ResNet-34 | $1 / 1$ | $52.4 \%$ | $-20.9 \%$ | (Lin, 2017) |
| ResNet-50 | $32 / 32$ | $76.0 \%$ | - | (Zhang, 2018) |
| ResNet-50 | $1 / 32$ | $72.8 \%$ | $-3.2 \%$ | (Yang, 2019) |

Chapter I

## I.7.6 Hardware Implementation of Binarized Neural Networks

## FPGA implementation

FPGAs are very used to accelerate BNNs when performing inference. Indeed, most CPUs and GPUs are optimized for executing integer and FP operations, but they may not be the best solution to execute bitwise operations efficiently. FPGAs allow for custom data paths, so that custom operations, such as XNOR and popcount operations, can be highly optimized. It should be noticed that FPGAs also contain DSPs, which can be fundamental when accelerating FP NNs models, but they are not used as extensively for BNNs, since bitwise operations are required. Compared with CPUs and GPUs, FPGA can accelerate a BNN with lower power consumption, even though the power stays in the range of tens of W. A list of FPGA implementations is reported in Table I.4, where all accuracy results refer to training on the CIFAR-10 dataset (Krizhevsky, 2009).

Table I. 4 Comparison of FPGA implementations of BNN accelerators. All accuracy results refer to training on the CIFAR-10 dataset (Krizhevsky, 2009).

## ASIC Implementation

As with FPGA, Application-Specific Integrated Circuits (ASICs) provide the possibility to implement a custom data path with custom arithmetic operations. ASICs provide by far the best performance both in terms of power consumption and frequency. On the other hand, a great effort is required to design integrated circuits, and the cost can be amortized only if the volume of production is huge. In Table I. 5 a list of ASIC implementations of BNN accelerators is reported. It can be seen that the power consumption is orders of magnitude lower than the one with FPGAs.

Table I. 5 Comparison of ASIC implementations of BNN accelerators.

Chapter I

## Chapter II Human Activity Recognition

## II. 1 Definition and Applications

Human Activity Recognition (HAR) is the ability to recognize human activities using sensors and it is a promising technology for many application fields. From an analytical point of view, let us imagine that a certain person is performing an activity belonging to a predefined set of activities $A$ :
$A=\left\{A_{i}\right\}_{i=1}^{N}$
where $N$ denotes the number of activities. The activity information is captured by a sequence of sensor readings:
$s=\left\{d_{1}, d_{2}, \ldots, d_{n}\right\}$
where $d_{t}$ denotes the sensor reading at time $t$. HAR aims to predict the activity sequence $A^{p}$ based on sensor reading $s$. To do that, a model $f$ must be built:

$$
\begin{equation*}
A^{p}=\left\{A_{j}^{p}\right\}_{j=1}^{n}=f(s), \quad A_{j}^{p} \in A \tag{36}
\end{equation*}
$$

where $n$ denotes the length of the sequence. The true activity sequence (ground truth) is denoted as $A^{t}$ :
$A^{t}=\left\{A_{j}^{t}\right\}_{j=1}^{n}, \quad A_{j}^{t} \in A$
In HAR, model $f$ must be learned by minimizing the discrepancy between the predicted activity $A^{p}$ and the ground truth activity $A^{t}$.

Based on the set of activities to be recognized, different applications can be found for HAR. In healthcare, it can be used for Parkinson's disease monitoring or rehabilitation purposes (Eskofier, 2016), (Bisio, 2016) (Abobakr, 2018). Also, HAR is widely used in assisted living, especially for elderly care (De, 2018). Other applications are video surveillance (Xian,

## Chapter II

2017), gesture recognition (Normani, 2018), gait analysis (Cola, 2017), fitness (Chinimilli, 2017).

## II. 2 Sensors in Human Activity Recognition Systems

HAR can be classified based on the type of sensor used to acquire data. In Table II. 1 a list of the most used sensors in HAR systems is provided. In particular, data can be acquired using either image sensors, such as cameras, or inertial sensors, such as accelerometers, gyroscopes, or other Inertial Measurement Units (IMUs). Physical health sensors are sometimes used with motion sensors to detect the activities of patients for rehabilitation purposes or capturing their vital signals for health condition evaluation (Chen, 2014). A key problem in HAR is where to place the sensors since different body parts provide different sensitivity to different activities, and hence different performance in terms of accuracy (Yu, 2016). As an example, placing an accelerometer at the ankle is expected to detect the motion information caused by legs or feet on the arm, thus allowing identifying activities like walking or running. On the other hand, an accelerometer placed at the chest might not measure the movements of arms.

Table II. 1 Most used sensors in HAR systems.

| Category | Sensor |
| :--- | :--- |
| Inertial Sensors | Accelerometer <br> Gyroscope <br> Magnetometer |
| Physical Health | Electrocardiogram (ECG) <br> Sensors |
|  | Hearth Rate (HR) |
|  | Electroencephalograph (EEG) |
| Electromyogram (EMG) |  |
| Environmental | Temperature |
| Sensors | Humidity |
|  | Light sensor |
|  | Barometer |
| Others | Camera |
|  | Microphone |
|  | GPS |

Another classification among HAR systems is based on the number of sensor positions and the number of types of sensors used. More precisely, four configurations can be identified:

- One to One: this is the basic modality in HAR systems, where one single sensor is placed at one single body part.
- One to Multi: in this configuration, one single type of sensor is placed at multiple body parts, thus obtaining complementary signals from different positions.
- Multi to One: in this configuration, a sensor device with more than one type of sensors built-in on one body part, aiming to capture different kinds of information
- Multi to Multi: in this last scenario, multiple devices, each embedded with one or more types of sensors, are placed at multiple body parts, thus combining the advantages of all the above configurations.
It should be noticed that better accuracies are to be expected by using more sensors. However, the higher the number of sensors, the higher is the complexity of the HAR system, and hence the power consumption. The most potential body positions that have been explored to deploy one or more sensors are hands, arms, wrists, chest, pockets, head, feet, shank, thighs, trunk, vest, waist, ankles, belt, pelvic, hip, legs, abdomen, back, knees, ears, neck.

To summarize, two major categories of HAR techniques can be identified: the first is usually named video-based HAR, while the second one is named Inertial-Sensor-based HAR (IS-HAR), or just sensor-based HAR. The continuous improvements of sensor technology, mainly in terms of reduced area and power consumption, as well as the increment of the processing power of portable devices in the era of pervasive computing, have been favored the development and the diffusion of IS-HAR systems. This thesis focus on the design of an ultra-low power smart sensor, thus ISHAR is a perfect candidate as a case study.

## II. 3 Classification Techniques

IS-HAR systems can be further classified based on the model used to achieve the classification. Classification can be achieved either through conventional PR methods (Bulling, 2014), such as Decision Trees, SVM, naïve Bayes, and hidden Markov, or through DL models (Yu, 2016), such as CNNs, autoencoder (AE), etc.

## II.3.1 Pattern Recognition methods

In a typical PR-based classification method, two main signal processing stages can be identified: first, a set of features are extracted from raw samples from the sensors, then a ML model is used to achieve classification based on the extracted features.

## Chapter II

## Feature Extraction

During feature extraction, a set of features are extracted from sensor data. More in detail, features are extracted as feature vectors $X_{i}$ from an input data window $w_{i}$. The total number of features extracted forms the feature space. The core idea is that activities that belong to the same class will be clustered in the same region of the feature space. In HAR systems, features need to be robust against user variability, that is features must not depend on the specific user who is performing the activity, as well as intraclass variability, that is the same activity must be clustered in the same region even though it can be performed in different ways. In the following, the most used features in HAR are listed below:

- signal-based features: these are mostly statistic features, such as mean, variance, kurtosis, and the like. These features are popular due to their simplicity as well as their high performance across a variety of HAR problems (Ravi, 2007). Also, frequency-domain features are sometimes used (Kang, 1995).
- body model features: these are calculated from a 3D skeleton using multiple on-body sensors (Zinnen, 2009). Polynomial features that describe signal trends such as mean, slope, and curvature are used for trajectories of limbs (Blanke, 2010)
- event-based features: these are extracted when a certain event occurs. An example is features extracted from repetitive eye movement sequences (Bulling, 2011).
- multilevel features: in this case, data is first clustered, for example using $k$-means. Then statistics like duration, frequency, and occurrence of data are encoded to provide expressive features.

## Classification

Many PR methods can be used to achieve classification in HAR systems. Among the most used ones, there are Hidden Markov Models (HMMs), Decision Trees, k-Nearest Neighbor (kNN), and Naïve Bayes. A list of references where PR methods are used for HAR purposes is provided in Table II. 2.

## II.3.2 Deep Learning methods

Despite PR methods allow achieving satisfactory accuracies in many cases, some drawbacks must be considered. Firstly, the features need to be extracted in a heuristic and hand-crafted way, which heavily relies on human expertise and domain knowledge. Even though human knowledge may help in certain task-specific settings, in general, this will result in a lower chance and a longer time to build a successful HAR system. Also, PR methods
allow achieving good accuracies only in classifying a limited number of activities, especially when more complex activities need to be recognized.

DL models tend to overcome those limitations, as they do not require feature extraction. Indeed, features can be automatically learned by the DL model itself, thanks to its deep multi-layered internal representation. Among the most used DL models in HAR, there are DNNs, CNNs, AEs, and Recurrent Neural Networks (RNNs). A list of references where PR methods are used for HAR purposes is provided in Table II.3.

Table II. 2 Examples of Pattern Recognition methods for Human Activity Recognition. The activities which are classified are specified for each case, as well as the accuracy and the sensors used to sample data.

## II. 4 Time-Latency Requirements in Human Activity Recognition

In addition to the accuracy level, latency is another factor that has often to be taken into account in HAR systems. Latency can be defined as the time that has elapsed from the beginning of an activity to its detection by the system (Dinarević, 2019). However, the particular HAR tasks must be distinguished to understand whether latency has to be actually minimized. In particular, low latency is an important requirement in all those applications where immediate feedback may be required, such as fall detection and epilepsy seizure detection. In those cases, high accuracy is not sufficient and an optimal trade-off should be investigated to guarantee an actual effective solution. Nevertheless, few studies report their achieved latency in the literature (Rault, 2017). For some other applications of HAR, such as the distance walked in a day and general daily activities, a higher latency can be accepted without compromising the validity of the solution.

The main model parameter that can be tuned to control the latency of the system is the window size. In fact, regardless of the classification technique, the data stream must be segmented in data windows for processing. The most widely used segmentation method in HAR is the sliding window approach (Banos, 2014). The signals are split into windows of a fixed size, with the possibility to have some overlap. Banos et al. (2014) proved that the best trade-off between recognition speed and accuracy is obtained within the window size interval 1-2 s.

Chapter II

## II. 5 Public Datasets for Human Activity Recognition

The importance of HAR among the current research topics is proven by the existence of several public datasets. Those datasets are fundamental to test a new model and fairly compare it with state-of-the-art. Below, some of the most used public datasets for HAR are briefly described.

## II.5.1 PAMAP2 dataset

The PAMAP2 Physical Activity Monitoring dataset (Reiss, 2012) contains data of 18 different physical activities, performed by 9 subjects wearing 3 IMUs and a heart rate monitor. Each IMU was placed in a different position. In particular, hand, chest, and ankle have been chosen. Each IMU was made up of a 3D accelerometer, 3D gyroscope, 3D magnetometer, and temperature. Two different scales are available for the 3 D accelerometer, which are $\pm 16 \mathrm{~g}$ and $\pm 6 \mathrm{~g}$. It should be noticed that due to high impacts caused by certain movements (especially running), the accelerometer with $\pm 6 \mathrm{~g}$ range gets sometimes saturated. The sampling frequency was set to 100 Hz . The heart rate sensor monitored the bpm of each subject, with a sampling frequency of approximately 9 Hz .

Each of the subjects had to follow a protocol, containing 12 different activities, which are: lying, sitting, standing, walking, running, cycling, Nordic walking, ascending stairs, descending stairs, vacuum cleaning, ironing, rope jumping. Furthermore, a list of optional activities to perform was also suggested to the subjects. From the list, in total 6 different activities were performed by some of the subjects in addition to the protocol. Namely, they are watching TV, computer work, car driving, folding laundry, house cleaning, playing soccer.

The dataset is not balanced, that is a different number of samples is associated with each activity. This is detailed in Table II.4, where the time in seconds for each activity is specified. Also, details about the PAMAP2 dataset are summarized in Table II.6.

## II.5.2 SHL dataset

The University of Sussex-Huawei Locomotion (SHL) dataset (Ciliberto, 2017) was collected at the University of Sussex. It was recorded over 7 months in 2017 by 3 users engaging in 8 different modes of transportation in a real-life setting in the United Kingdom. More in detail, the SHL dataset, where labels are: Car, Bus, Train, Subway, Walk, Run, Bike, and Still. The dataset contains multi-modal data from a body-worn camera and 4 smartphones, carried simultaneously at typical body locations, that are Bag, Hand, Hips, and Torso. All data is sampled at 100 Hz by using the following sensors: 3D accelerometer, 3D gyroscope, 3D magnetometer, pressure
sensor, and temperature sensors. As for the PAMAP2 dataset, the SHL dataset is not balanced. Details about the amount of data per class are reported in Table II.5, whereas generic details about the SHL dataset are summarized in Table II. 6.

Table II. 4 Available time window in seconds for each activity in the PAMAP2 dataset. An ID is associated with each activity. Also, a check sign is used to identify the 6 optional activities.

| ID |  | Activity | Optional |
| :--- | :--- | :---: | :--- | Available time window [s]

Table II. 5 Available time window in hours for each activity in the SHL dataset. An ID is associated with each activity

| ID | Activity | Available time window <br> [h] |
| :---: | :---: | :---: |
| 1 | Still | 127 |
| 2 | Walking | 127 |
| 3 | Run | 21 |
| 4 | Bike | 79 |
| 5 | Car | 88 |
| 6 | Bus | 107 |
| 7 | Train | 115 |
| 9 | Subway | 89 |
| Total: 753 |  |  |

Table II. 6 Summary of SHL and PAMAP2 public datasets. For each dataset, the following features are specified: number of classes, sensors used to sample data, sampling frequency for each sensor, possible carry positions.

| Dataset | \#classes | Sensors | Sampling Frequency | Positions |
| :---: | :---: | :---: | :---: | :---: |
| PAMAP2 | 12+6 | 3D accelerometer ( $\pm 6 \mathrm{~g}$ scale) | 100 Hz | Ankle Hand Chest |
|  |  | $\begin{aligned} & \text { 3D accelerometer } \\ & ( \pm 16 \mathrm{~g} \text { scale }) \end{aligned}$ | 100 Hz |  |
|  |  | 3D gyroscope | 100 Hz |  |
|  |  | 3D magnetometer | 100 Hz |  |

|  |  | Pressure sensor | 100 Hz |  |
|  |  | Temperature sensor | 100 Hz |  |

## II. 6 HW Solutions for Human Activity Recognition

Even though a lot of research is being carried out on HAR, in most of the literature, the development of a HAR system is associated with the development of algorithms or models, and most of the efforts are made to achieve high accuracy. Unfortunately, such high accuracies are obtained using MCUs, CPUs, or GPUs, and those systems are not embeddable on ultra-low power wearable devices or smart sensors due to their high power consumption.

Nicosia et al. (2018) addressed this problem by exploiting a light harvester to improve the lifetime of a sensor-rich wearable node. The module is based on a 32-bit MCU, which features a Floating-Point Unit (FPU) single-precision (32-bit), 128 KB of RAM, and 1 MB of Flash ROM. In addition, the module features many Micro Electrical Mechanical Systems (MEMS) sensors, such as accelerometers, gyroscope, and magnetometer, and environmental sensors, such as pressure, humidity, and temperature sensors. The MCU is able to run a 5-layer CNN, which achieves an average accuracy of $96.13 \%$ when classifying 5 different activities, i.e. stationary, walking, running, biking, and driving. The samples are acquired using a 3D accelerometer with a sampling frequency of 26 Hz . Measurements show that the current absorbed by the board in dark conditions is 1.75 mA .

However, to obtain more energy-efficient systems, a dedicated HW circuitry should be designed, which is the objective of the research activity in this thesis. In the following, the only works found in the literature that
propose a dedicated HW accelerator for HAR applications are briefly described.

Hanai et al. (2009) presented a versatile recognition processor, which is able to perform detection and recognition of image, video, and acceleration signals. Concerning HAR, the processor can recognize human activities such as walking, reading, and typing from short and low-quality 3D acceleration signals, with a time window from 2 s to 10 s . Data is sampled at 50 Hz with a resolution of 8 -bit. The classification is achieved using Haar-like features and cascaded filters. The processor is fabricated in 90 nm CMOS technology, occupies $0.89 \mathrm{~mm}^{2}$, and runs at 54 MHz with a 0.9 V supply. For activity recognition from 8 -bit 50 Hz acceleration signals, the power consumption per frame rate is $0.15 \mu \mathrm{~W} / \mathrm{fps}$ with an accuracy of $93 \%$.

In the paper by Kodali et al. (2017), seven different IoT applications were implemented using a FC DNN accelerator designed in 28 nm CMOS technology. Among the various applications, HAR is performed. The accuracy has been estimated for 5 different public HAR datasets. The best accuracy has been obtained for the Smartphone-based Human Activity Recognition Feature-Extracted dataset and is equal to $93.6 \%$. The HW accelerator can operate with a supply voltage as low as 0.56 V . With this voltage level, and with a frequency of 443 MHz , the power consumption is equal to 1.12 mW . Based on this operating point, the authors have derived an estimate of the power consumption for each application. The results are summarized in Table II.7. It must be noticed that the authors did not take into account the power dissipation due to leakages, which can be significant when scaling down the frequency in a 28 nm CMOS technology.

In the work of Jafari et al. (2019), a scalable and low-power embedded deep CNN named SensorNet is presented, which allows classifying multimodal time-series signals. A custom low-power hardware architecture has been designed to allow the deployment of the CNN model in an embedded real-time system. SensorNet performance is evaluated using 3 different case studies, including HAR. When performing HAR, the model achieves $98.0 \%$ accuracy. The architecture is implemented with CMOS 65 nm technology, and results show a total power consumption of 18.5 mW when the throughput is $67 \mathrm{label} / \mathrm{s}$. This throughput is obtained with a clock frequency of 100 MHz .

| Smartphone <br> (FE) | 39.5 | 99.9 | 128.1 |

# Chapter III <br> Orientation Estimation in Inertial Sensors 

## III. 1 Device-Orientation problem

Inertial sensors measure motion-related physical quantities, such as acceleration, angular rate, etc. For this kind of measurement, it is very important to define which is the reference frame. As an example, a 3-axis accelerometer provides the components of the measured acceleration on the three axes defined by its own orientation in the space. Looking at Figure III.1, the components of the measured accelerations are provided on the axis $x, y$, and $z$. Therefore, it is easy to realize that the physical meaning associated with the acceleration measured on each axis is strongly dependent on the orientation of the sensors. This is not a trivial issue, especially when the sensor is embedded in portable or wearable devices, such as smartphones or smartwatches. Indeed, it is not possible to know in advance which will be the orientation of the device, thus making it very difficult to extract useful features from the raw measurement. This problem is known as the deviceorientation problem, and it is especially present in IS-HAR systems, where the sensor cannot keep a fixed orientation in the space due to human movements, and it can often be placed in different positions as well. In this context, 3 different reference frames are defined in the paper by Jahn et al. (2017): the Device Coordinate System (DCS), which is the reference frame defined by the orientation of the sensor, the World Coordinate System (WCS), that is the reference frame relative to the world's gravity force and the magnetic north; the User Coordinate System (UCS), that is the reference frame defined by the user's heading. The latter can be useful to track the movements of a person or an object. More generally, many solutions have been proposed in the literature to mitigate the effects of the unknown orientation in inertial sensors by transforming the measurements from the DCS to the WCS. A graphical representation of DCS and WCS is provided in Figure III.1. In all cases, some signal processing operations must be

## Chapter III

performed on the raw measurement data, such as filtering, 3D rotations, and the like. Unfortunately, the computational complexity of such operations does not fit with the capabilities of wearable devices, where the HW resources are limited and the energy consumption is constrained to be as low as possible. During the first part of my research activity, I focused on the definition of an HW-friendly algorithm to solve the device-orientation problem in 3-axis accelerometers.

Figure III. 1 Graphical representation of the 2 possible reference frames for an inertial sensor. The Device Coordinate System is the reference frame defined by the device (solid line in the figure). The World Coordinate System is the reference frame defined by the world's gravity force (dotted line in the figure). In this figure, the World Coordinate System is defined as the reference frame whose $z$-axis is opposite to the gravity vector, $g$.

## III. 2 State-of-the-art solutions to the device-orientation problem

In this paragraph, many solutions to the device-orientation problem will be presented. Three different cases can be detected based on the sensors which are used in the system: accelerometer + magnetometer, accelerometer + gyroscope, only accelerometer.

## III.2.1 Accelerometer + Magnetometer

As explained above, the raw measurements need to be transformed from the DCS to the WCS to cancel the dependence from the sensor orientation. A solution can be to exploit the measurement of the north direction provided by a magnetometer. In the paper by Ustev et al. (2013), the orientation angle is computed by using both the accelerometer and the magnetometer embedded in a smartphone. When the device is not subject to an external acceleration, it measures the gravity acceleration pointing towards the center of the Earth. This allows computing the tilt angles. At the same time, the magnetometer provides the magnetic vector in the three axes of the DCS. By
fusing data from the accelerometer and magnetometer, it is possible to detect the orientation of the device. The authors collected data from 20 participants, who were asked to perform locomotive activities (i.e., running, standing, biking, sitting, walking). All activities were performed for 3 minutes and a total of 15 minutes of movement data was collected from every participant. Different kinds of tests were performed using a k-NN classifier to measure accuracy. During the orientation tests, the device was carried in different orientations to investigate the orientation dependency. Three different orientation tests were performed based on the input data:

1. in the first test, the input data was the raw measurement from the accelerometer;
2. in the second test, data from the accelerometer was fused with the magnetometer data to detect the orientation of the device. Then, the gravity component on each axis can be isolated to obtain the linear acceleration;
3. in the third test, the linear acceleration was converted from the DCS to the WCS.
The accuracy results are summarized in Table III.1. The highest accuracy is obtained when the conversion from the DCS to the WCS is performed.

Table III. 1 Results from the orientation test for different input data (Ustev, 2013).

| Test | Accuracy |
| :---: | :---: |
| 1 | $83 \%$ |
| 2 | $93 \%$ |
| 3 | $97 \%$ |

## III.2.2 Accelerometer + Gyroscope

Another solution to perform the transformation from the DCS to the WCS can be to use both an accelerometer and a gyroscope. Florentino-Liaño et al. (2012) computed the inclination of the sensor in terms of the angles of roll, $\theta_{x}$, and pitch, $\theta_{y}$, by using the following formulas:

$$
\begin{equation*}
\theta_{x}=\arctan \left(\frac{\overline{a_{y}^{D C S}}}{\overline{a_{z}^{D C S}}}\right) \tag{38}
\end{equation*}
$$

$\theta_{y}=\arcsin \left(\frac{-\overline{a_{x}^{D C S}}}{\sqrt{\left(\overline{a_{x}^{D C S}}\right)^{2}+\left(\overline{a_{y}^{D C S}}\right)^{2}+\left(\overline{a_{z}^{D C S}}\right)^{2}}}\right)$

## Chapter III

where $\overline{a_{x}^{D C S}}, \overline{a_{y}^{D C S}}$, and $\overline{a_{z}^{D C S}}$ are the means of the measured acceleration in the DCS obtained during periods of little or no linear acceleration. It should be noticed that it is not possible to determine the angle of yaw, $\theta_{z}$, by using only an accelerometer and gyroscope. However, this is not an issue in HAR, because it is not important if the user is facing towards North or in any other direction. Using (38) and (39), and assuming a yaw angle of zero, a rotation matrix is defined to partially transform the measurements from the DCS to the WC as in (40).

$$
\left(\begin{array}{ccc}
\cos \left(\theta_{y}\right) & \sin \left(\theta_{x}\right) \sin \left(\theta_{y}\right) & \cos \left(\theta_{x}\right) \sin \left(\theta_{y}\right)  \tag{40}\\
0 & \cos \left(\theta_{x}\right) & -\sin \left(\theta_{x}\right) \\
-\sin \left(\theta_{y}\right) & \sin \left(\theta_{x}\right) \cos \left(\theta_{y}\right) & \cos \left(\theta_{x}\right) \cos \left(\theta_{y}\right)
\end{array}\right)
$$

Once the initial orientation has been computed in this manner, the angular velocity can be integrated over time to update the rotation matrix. Florentino-Liaño et al. (2012) point out that always transforming the data from the DCS to the UCS does not help to distinguish between low-motion activities, such as standing, sitting, and lying. Indeed, the only acceleration that is measured in those cases is the gravity acceleration, which will always be contained in the $z_{t}$ direction ( $\mathrm{z}_{t}$ is defined in Figure III.1). To solve this problem, the transformation can be only performed once, while the user is standing still.

## III.2.3 Only Accelerometer

The problem of the device orientation can also be solved by using only an accelerometer. This can be the best choice when there are power and area constraints. In the work of Mizell (2003), a solution was proposed to estimate the accelerometer orientation using a single tri-axial accelerometer only. For a chosen sampling interval, typically a few seconds, an estimate of the gravity component on each axis is obtained by averaging all the measurements in the sampling interval on the respective axis. This corresponds to estimate the gravity vector $g=\left(g_{x}, g_{y}, g_{z}\right)$, where $g_{x}, g_{y}$, and $g_{z}$ are the averages of all the measurements in the sampling interval on the $x, y$, and $z$ axis respectively. Let $a=\left(a_{x}, a_{y}, a_{z}\right)$ be the vector made up of the three acceleration measurements taken at a given point in the sampling interval. Thus, the linear acceleration can be computed as:
$v=\left(a_{x}-g_{x}, a_{y}-g_{y}, a_{z}-g_{z}\right)$
Then, the linear acceleration in (41) is projected on the gravity vector $g$ using the dot product, thus obtaining $p$ :

$$
\begin{equation*}
p=\left(\frac{v \cdot g}{g \cdot g}\right) g \tag{42}
\end{equation*}
$$

In other words, $p$ is the component of the linear acceleration in the direction of the gravity vector, i.e. the "vertical component" of the linear acceleration. Since a 3D vector is the sum of its vertical component and horizontal component, the latter can be computed simply by vector subtraction.

## III. 3 Proposed Solution

A solution to the device-orientation problem is proposed in this thesis. Considering that the aim is to develop an ultra-low power smart sensor, a signal processing technique has been defined which takes in input data from a single 3D accelerometer. The application that has been considered is HAR. In the proposed solution, the measured acceleration is transformed from the DCS to the WCS in two stages: the filtering stage and the vector rotation stage. In the first one, the gravity acceleration is isolated from the measured acceleration, and it is used as a reference in the vector rotation stage to define the WCS. In particular, the WCS has been defined as the reference frame in which the $z$-axis is opposite to the gravity vector.

## III.3.1 Filtering Stage

In the filtering stage, the components of the acceleration acquired by the tri-axial accelerometer are filtered to separate the high-frequency component from the low frequency/DC component. The latter roughly corresponds to the gravity acceleration, while the former is related to human motion. The filter is a $4^{\text {th }}$ order high-pass IIR Butterworth filter, with a cutoff frequency of 0.4 Hz . The main characteristics of the filter are summarized in Table III.2, where $f_{-3 d B}$ is the -3 dB cutoff frequency, and $f_{c}$ is the sampling frequency. The sampling frequency has been selected considering the typical ones in HAR (Bulling, 2014).

Table III. 2 Initial filter specifications

| Filter Response | Frequency Behavior | $f_{-3 d B}$ | Order | $f_{c}$ |
| :---: | :---: | :---: | :---: | :---: |
| IIR Butterworth | High-pass | 0.4 Hz | 4 | 25 Hz |

## IIR Filters

A causal IIR filter (Mitra, 2000) is described in (43):

Chapter III

$$
\begin{equation*}
\sum_{k=0}^{N} d_{k} y[n-k]=\sum_{k=0}^{M} p_{k} x[n-k] \tag{43}
\end{equation*}
$$

where $x[n]$ is the input sequence, $y[n]$ is the output sequence, $h[n]$ is the impulsive response, $\left\{d_{k}\right\}$ and $\left\{p_{k}\right\}$ are real coefficients. The equation in (43) can be rewritten as:
$y[n]=-\sum_{k=1}^{N} \frac{d_{k}}{d_{0}} y[n-k]+\sum_{k=0}^{M} \frac{p_{k}}{d_{0}} x[n-k], \quad d_{0} \neq 0$
From (44), it is clear that the output of the filter can be computed using a recursive method. Applying the Z-transform to (43), the transfer function of an IIR filter is obtained:

$$
\begin{equation*}
H(z)=\frac{p_{0}+p_{1} z^{-1}+\ldots+p_{M-1} z^{-(M-1)}+p_{M} z^{-M}}{d_{0}+d_{1} z^{-1}+\ldots+d_{N-1} z^{-(N-1)}+d_{N} z^{-N}}=\frac{p_{0}}{d_{0}} \frac{\prod_{l=1}^{M}\left(1-\xi_{l} z^{-l}\right)}{\prod_{l=1}^{N}\left(1-\lambda_{l} z^{-l}\right)} \tag{45}
\end{equation*}
$$

Using (45), the filter can be described using $\xi_{l}$ and $\lambda_{l}$, which are zeros and poles of the transfer function $H$ respectively. For values of $z$ in the region $|z|=1$, known as the unit circle, the transfer function can be expressed as a function of a single real variable, $\omega$, by defining $z=e^{j \omega}$. This corresponds to the Discrete-Time Fourier Transform (DTFT).

## Structure Identification

The structure of the filter has been identified to minimize the required HW resources. In particular, a Coupled-All Pass structure has been adopted, in which the number of the required multipliers and registers is equal to the order of the filter. A comparison with other well-known filter structures is shown in Table III.3, in which $N$ is the order of the filter. The comparison shows that the Couple All-Pass structure requires about N multipliers less, and about N adders more than the other two structures. Since a multiplier requires much more resources than an adder, the Coupled All-Pass form is the most convenient structure in terms of required resources. The scheme of a Coupled All-Pass filter is represented in Figure III.2.

Table III. 3 Required HW resources for different filter structures.

| Filter Structure | \#Mult | \#Reg | \#Adders |
| :---: | :---: | :---: | :---: |
| II Direct Form | $2 N+1$ | $2 N+1$ | $2 N$ |
| Transposed | $2 N+1$ | $2 N+1$ | $2 N$ |
| Cascaded Form | $N$ | $N$ | $3 N+2$ |
| Coupled All-Pass |  |  |  |

Figure III. 2 Coupled All-Pass realization of $G(z)$ and its power complementary function $H(z)$.

## Coupled All-Pass filters

A Coupled All-Pass filter is based on the concept of power complementary property of the transfer functions (Vaidyanathan, 1986). Consider the following transfer function:
$G(z)=\frac{P(z)}{D(z)}=\frac{p_{0}+p_{1} z^{-1}+\ldots+p_{N-1} z^{-(N-1)}+p_{N} z^{-N}}{d_{0}+d_{1} z^{-1}+\ldots+d_{N-1} z^{-(N-1)}+d_{N} z^{-N}}$
In (46), assume that $P(z)$ is symmetric, i.e. $p_{k}=p_{N-k}$. If $G(z)$ is either a high-pass or low-pass Butterworth, Chebyshev, or elliptic filter, and if the has odd order, it can be expressed as the sum of two all-pass transfer function $A_{1}(z)$ and $A_{2}(z)$ :
$G(z)=\frac{1}{2}\left[A_{2}(z)+A_{1}(z)\right]$
Also, we can define the transfer function $H(z)$ as:
$H(z)=\frac{1}{2}\left[A_{2}(z)-A_{1}(z)\right]$
The two transfer functions $G(z)$ and $H(z)$ are power complementary, that is:
$\left|G\left(e^{j \omega}\right)\right|^{2}+\left|H\left(e^{j \omega}\right)\right|^{2}=1$
In the same way as $G(z), H(z)$ can be written as:
$H(z)=\frac{Q(z)}{D(z)}=\frac{q_{0}+q_{1} z^{-1}+\ldots+q_{N-1} z^{-(N-1)}+q_{N} z^{-N}}{d_{0}+d_{1} z^{-1}+\ldots+d_{N-1} z^{-(N-1)}+d_{N} z^{-N}}$
In (50), $Q(z)$ is symmetric, i.e. $q_{k}=q_{N-k}$. The equations (47) and (48) are represented by the scheme in Figure III.2. The all-pass transfer functions can be easily identified using the following method: if $\lambda_{0}, \lambda_{1}, \ldots, \lambda_{N}$, are the poles

## Chapter III

of $G(z)$, and if they are ordered so that $\angle\left(\lambda_{k}\right)<\angle\left(\lambda_{k+1}\right)$, the odd-indexed poles belong to $A_{2}(z)$, while the even-indexed poles and the zero-indexed poles belong to $A_{1}(z)$. Also, thanks to the power complementary property, if $G(z)$ is a low-pass transfer function, then $H(z)$ is a high-pass filter function, and vice versa. Moreover, the power complementary property guarantees that the two transfer functions have the same cutoff frequency. Based on the above, the problem of identifying the structure for the desired filter is converted to the problem of identifying the structures of the all-pass filters. Whatever filter structure, in principle, could be used for this purpose. However, to minimize the required hardware resources and obtain the advantages shown in Table III.3, the two pair extraction approach (Vaidyanathan, 1986) has been used. This approach is described in the following. Consider an $m^{\text {th }}$ all-pass transfer function:

$$
\begin{equation*}
A_{m}(z)=\frac{d_{m}+d_{m-1} z^{-1}+\ldots+d_{1} z^{-(m-1)}+d_{0} z^{-m}}{d_{0}+d_{1} z^{-1}+\ldots+d_{m-1} z^{-(m-1)}+d_{m} z^{-m}} \tag{51}
\end{equation*}
$$

In an all-pass transfer function, the coefficients in the numerator are the same coefficients of the denominator but with the opposite order. From (51), it is possible to obtain an $(m-1)^{\text {th }}$ all-pass transfer function using the following relationship:

$$
\begin{equation*}
A_{m-1}(z)=z \frac{A_{m}(z)-k_{m}}{1-k_{m} A_{m}(z)}=\frac{d_{N}^{\prime}+d_{N-1}^{\prime} z^{-1}+\ldots+d_{1}^{\prime} z^{-(N-1)}+z^{-N}}{1+d_{1}^{\prime} z^{-1}+\ldots+d_{N-1}^{\prime} z^{-(N-1)}+d_{N}^{\prime} z^{-N}} \tag{52}
\end{equation*}
$$

where:
$k_{m}=A_{m}(\infty)=d_{m}$
$d_{i}^{\prime}=\frac{d_{i}-d_{m} d_{m-i}}{1-d_{m}^{2}}$
Thus, $A_{m}(z)$ can be obtained from (52):

$$
\begin{equation*}
A_{m}(z)=\frac{k_{m}+z^{-1} A_{m}(z)}{1+k_{m} z^{-1} A_{m}(z)} \tag{54}
\end{equation*}
$$

At this point, a two pair can be considered, i.e. a discrete-time Linear Time-Invariant (LTI) system with two inputs and two outputs. Say $X_{1}, X_{2}$ the inputs and $Y_{1}, Y_{2}$ the outputs, and assume that $X_{2}=A Y_{2}$, as represented in XXX. It can be shown that the behavior of such a system can be described by the equations:
$Y_{1}=k_{m} X_{1}+\left(1-k_{m}\right) z^{-1} X_{2}$
$Y_{2}=\left(1+k_{m}\right) X_{1}+k_{m} z^{-1} X_{2}$

Defining $V_{1}=k_{m}\left(X_{1}-z^{-1} X_{2}\right)$, the equations in (55) can be rewritten as:
$Y_{1}=V_{1}+z^{-1} X_{2}$
$Y_{2}=X_{1}+V_{1}$
In the end, the mth order all-pass transfer function, $A_{m}(z)$, has been represented as a function of the $(m-1)^{\text {th }}$ order all-pass transfer function, $A_{m-1}(z)$, as depicted in Figure III.4. In Figure III.5, the structure that implements the equations (55) is shown.

Figure III. 3 Schematic representation of a two-pair with a constraint on the second port.

Figure III. 4 Two pair representation of $A_{m}(z)$.

Figure III. 5 Realization of the two-pair using a single multiplier.

The procedure described above can be repeated recursively until the allpass function $A_{0}(z)$ is realized. As a result, $A_{m}(z)$ is realized using $m$ all-pass cascaded cells as shown in Figure III.6. From Figure III.6, it is evident that using the two-pair extraction approach, the realization of an $m^{\text {th }}$ order all-

## Chapter III

pass filter requires $m$ registers and $m$ multipliers. Since the realization of an $N^{\text {th }}$ order coupled all-pass filter requires two all-pass filters, whose orders sum up to $N$, the realization of the whole filter requires $N$ registers and $N$ multipliers, according to Table III.3.

Figure III. 6 Realization of an $m^{\text {th }}$ order all-pass filter using the two-pair extraction approach, in which the two-pair is realized using a single multiplier.

## Filter Design

Starting from the specifications in Table III.2, the filter has been implemented using a Coupled All-Pass structure. However, the implementation of a Coupled All-Pass filter requires the order to be odd, while the order specified in Table III. 2 is even (and equal to 4). This problem has been addressed by changing the order to 5 . The modified specifications are reported in Table III. 4 .

Table III. 4 Filter specifications for a coupled all-pass implementation.

| Filter Response | Frequency Behavior | $f_{-3 d B}$ | Order | $f_{c}$ |
| :---: | :---: | :---: | :---: | :---: |
| IIR Butterworth | High-pass | 0.4 Hz | 5 | 25 Hz |

The frequency response has been approximated using fdatool, a tool available in MATLAB for the design of filters. Using the specifications in Table III.4, the following transfer function has been obtained:

$$
\begin{equation*}
H(z)=\frac{0.922-4.609 z^{-1}+9.219 z^{-2}+9.219 z^{-3}+4.609 z^{-4}-0.922 z^{-5}}{1-4.837 z^{-1}+9.362 z^{-2}-9.063 z^{-3}+4.387 z^{-4}-0.850 z^{-5}} \tag{57}
\end{equation*}
$$

In Figure III.7, the amplitude of the transfer function is represented as a function of the normalized frequency (with respect to the sampling frequency).

Figure III. 7 Ideal frequency response of the filter; the frequency response around the normalized cutoff frequency is shown in detail.

## Sizing the wordlength

The original SW model performed the filtering operation using a FP double-precision (64-bit) encoding but, in order to minimize the area occupation and the power consumption of the proposed HW solution, the filter has been implemented using a Fixed-Point encoding. However, the resolution of a FP encoding is much lower than the resolution of a FI one. Thus, using a FI encoding, an error is introduced in the representation of the filter coefficients. As a consequence, also poles and zeros of the filter experience variations with respect to their theoretical value, and in the worstcase scenario the filter could become unstable. In Figure III.8, the comparison between the ideal frequency response of the high-pass Coupled All-Pass filter and the quantized ones is shown. The frequency response obtained with a FP 64 -bit encoding can be considered as the ideal one. Decreasing the number of bits used to represent the coefficients from 32 to 20, the difference becomes larger. By carrying out the same analysis for the low-pass frequency response, analogous results have been obtained (Figure III.9). The filter is stable for all the considered word-length. Based on this analysis, a 24-bit FI encoding has been chosen to represent the coefficients. In this case, for both the high-pass and the low-pass frequency responses, the cutoff frequency has an error of the $0.19 \%$, which can be considered negligible.

Using (53), the coefficients $k_{1}, \ldots, k_{5}$ for the Coupled All-Pass filter have been obtained, which scheme is represented in Figure III.10.

## Chapter III

Figure III. 8 Comparison between the high-pass frequency response obtained using filter coefficients represented in FP 64-bit encoding (HFL64), assumed as the ideal frequency response, and the high-pass frequency responses obtained using filter coefficients represented in FI 32bit (H-FI32), FI 28-bit (H-FI28), FI 24-bit (H-FI24), FI 20-bit (H-FI20). The filter is realized using a Coupled All-Pass structure.

Figure III. 9 Comparison between the high-pass frequency response obtained using filter coefficients represented in FP 64-bit encoding (HFL64), assumed as the ideal frequency response, and the high-pass frequency responses obtained using filter coefficients represented in FI 32bit (H-FI32), FI 28-bit (H-FI28), FI 24-bit (H-FI24), FI 20-bit (H-FI20). The filter is realized using a Coupled All-Pass structure.

Figure III. 10 Realization of the filter using a Coupled All-Pass structure.

## III.3.2 Vector Rotation Stage

The operations performed during the vector rotation stage aim to obtain a vector representation of the measured acceleration in a coordinate system where the $z$-axis has the same direction as the gravity vector. As depicted in Figure III.1, the tri-axial accelerometer defines the DCS as $S=\{x, y, z\}$, while gravity defines the WCS as $T=\left\{x_{t}, y_{t}, z_{t}\right\}$. When the sensor lies in a plane parallel to the ground surface, the overlap between $S$ and $T$ occurs. In all the other cases, acceleration data from the sensor are expressed by three coordinates in $S$. The three associated coordinates in $T$ are computed during the vector rotation stage. In geometric terms, $T$ is obtained through a rotation of $S$ around the rotation axis $u$ by an angle $\theta$, where $u$ and $\theta$ are defined in terms of the gravity vector $g$ as follows:

$$
\begin{align*}
& \hat{u}=\frac{\vec{g} \times \hat{z}}{\|\vec{g} \times \hat{z}\|}=\left(\frac{g_{y}}{g_{x y}},-\frac{g_{x}}{g_{x y}}, 0\right), \quad g_{x y}=\sqrt{g_{x}^{2}+g_{y}^{2}}  \tag{57}\\
& \theta=\cos ^{-1}\left(\frac{g_{z}}{\|\vec{g}\|}\right), \quad\|\vec{g}\|=\sqrt{g_{x}^{2}+g_{y}^{2}+g_{z}^{2}} \tag{58}
\end{align*}
$$

## Rotation algorithms

The mathematical operation performed in the vector rotation stage is a 3D rotation. The first step in the signal processing definition has been to identify the most suitable rotation algorithm. Four approaches are mainly used in the literature for vector orientation recalculation (Kok, 2017), (Janota, 2015): the

## Chapter III

Euler angles, which express the rotation of a vector in the space as three consecutive rotations around coordinate axes; the rotation matrix, which is calculated from the Euler angles but it is often preferred to them because of singularities, as happens in the work of Wu et al. (2016) for attitude estimation; the Rodrigues' rotation formula (or Euler's rotation vector) (Dai, 2015), which expresses the rotation between two coordinate frames in terms of an angle and a unit vector around which the rotation takes place, as in the work of Ginting et al. (2018) for the attitude control of a quadrotor; the unit quaternions, which use an alternative 4-dimensional representation of the orientation to avoid the gimbal lock issue of Euler angles (Kok, 2017), as in the paper by Emokpae et al. (2018) for the estimation of finger orientations in a smart glove for rehabilitation therapy. It is worth noting that all the above approaches describe the same quantities and, hence, can be used interchangeably. Regardless of the specific issues, the differences between them are essentially in the computational effort to process raw data from the sensors.

## Proposed rotation algorithm

All these techniques require a large number of arithmetical operations and they also involve the computation of trigonometric functions, divisions, and square roots. Thus, a new hardware-friendly algorithm has been developed which aims to define a modular calculation scheme. Modularity allows identifying a minimum set of operations per cycle to carry out the entire GR operation. Therefore, a very reduced set of operations can be identified, and, taking advantage of the very low sample rate $(25 \mathrm{~Hz})$ of the LIS2DW12 accelerometer, many cycles can be executed before a new sample is acquired.

The proposed algorithm assumes that $\hat{z}_{t}$ is defined by $\vec{g}$, namely:

$$
\begin{equation*}
\hat{z}_{t}=-\frac{\vec{g}}{\|\vec{g}\|}=-\left(-\frac{g_{x}}{\|\vec{g}\|},-\frac{g_{y}}{\|\vec{g}\|},-\frac{g_{z}}{\|\vec{g}\|}\right) \tag{59}
\end{equation*}
$$

To obtain $\hat{x}_{t}, \hat{x}$ must rotate in the same way as $\hat{z}$. To this end, $\hat{x}_{t}$ can be expressed as:

$$
\begin{align*}
& \hat{x}_{t}=\vec{x}_{u}+\vec{x}_{n}=\left(-\frac{\left|g_{x}\right| g_{x} g_{z}}{\|\vec{g}\| g_{x y}^{2}}+\frac{g_{y}^{2}}{g_{x y}^{2}},-\frac{\left|g_{x}\right| g_{y} g_{z}}{\|\vec{g}\| g_{x y}^{2}}-\frac{g_{x} g_{y}}{g_{x y}^{2}}, \frac{\left|g_{x}\right|}{\|\vec{g}\|}\right)  \tag{60}\\
& \vec{x}_{u}=(\hat{x} \cdot \hat{u}) \hat{u} \quad \vec{x}_{n}=\|\hat{x}-(\hat{x} \cdot \hat{u}) \hat{u}\|\left(\hat{z}_{t} \times \hat{u}\right)
\end{align*}
$$

where $\vec{x}_{u}$ is the component of $\hat{x}_{t}$ parallel to $\hat{u}$, and $\vec{x}_{n}$ is the component of $\hat{x}_{t}$ perpendicular to $\hat{u}$. Finally:

$$
\begin{equation*}
\hat{y}_{t}=\hat{z}_{t} \times \hat{x}_{t}=\left(\frac{a_{y} g_{z}-a_{z} g_{y}}{\|\vec{g}\|}, \frac{a_{z} g_{x}-a_{x} g_{z}}{\|\vec{g}\|}, \frac{a_{x} g_{y}-a_{y} g_{x}}{\|\vec{g}\|}\right) \tag{61}
\end{equation*}
$$

where (59) has been redefined as $\hat{x}_{t}=\left(a_{x}, a_{y}, a_{z}\right)$ for convenience. The WCS, $T$, is completely defined by (59)-(61). So, the components of the acceleration vector in $T,\left(v_{x r}, v_{y r}, v_{z r}\right)$, can be obtained by projecting the acceleration vector in $S, v=\left(v_{x}, v_{y}, v_{z}\right)$, onto $\left\{x_{t}, y_{t}, z_{t}\right\}$ :

$$
\begin{equation*}
v_{x r}=\vec{v} \cdot \hat{x}_{t}, \quad v_{y r}=\vec{v} \cdot \hat{y}_{t}, \quad v_{z r}=\vec{v} \cdot \hat{z}_{t} \tag{62}
\end{equation*}
$$

In Figure III. 11 a block diagram of the derived algorithm is represented, where the divisions in (59)-(61) have been grouped as a unique final step. In this way, the scheme reveals a repetition pattern: 2 or 3 parallel multiplications are followed by either a sum or two cascaded sums. This pattern can be used as a basic building block to implement the entire scheme. To this purpose, (59)-(61) must be rewritten in terms of de-normalized vectors:

$$
\begin{align*}
& \vec{x}_{d n_{-} t}=g_{x y}^{2}\|\vec{g}\| \hat{x}_{t}=\left(i_{x}, i_{y}, i_{z}\right)=  \tag{63}\\
& \left(-\left|g_{x}\right| g_{x} g_{z}+\|\vec{g}\| g_{y}^{2},-\left|g_{x}\right| g_{y} g_{z}-\|\vec{g}\| g_{x} g_{y}, g_{x y}^{2}\right) \\
& \vec{y}_{d n_{-} t}=g_{x y}^{2}\|\vec{g}\|^{2} \hat{y}_{t}=\left(j_{x}, j_{y}, j_{z}\right)= \\
& \left(i_{y} g_{z}-i_{z} g_{y}, i_{z} g_{x}-i_{x} g_{z}, i_{x} g_{y}-i_{y} g_{x}\right)  \tag{64}\\
& \vec{y}_{d n_{-} t}=\|\vec{g}\| \hat{z}_{t}=\left(k_{x}, k_{y}, k_{z}\right)=\left(-g_{x},-g_{y},-g_{z}\right) \tag{65}
\end{align*}
$$

As a consequence, also (62) must be rewritten as:
$v_{x r}=\frac{\vec{v} \cdot \vec{x}_{d n-t}}{g_{x y}^{2}\|\vec{g}\|}, \quad v_{y r}=\frac{\vec{v} \cdot \vec{y}_{d n-t}}{g_{x y}^{2}\|\vec{g}\|^{2}}, \quad v_{z r}=\frac{\vec{v} \cdot \vec{z}_{d n^{\prime}-t}}{\|\vec{g}\|}$
In Table III.5, the computational effort of many rotation techniques has been compared with the proposed one in terms of the number of additions, multiplications, and additional mathematical functions required to process a generic rotation, starting from raw data provided by a tri-axial accelerometer.

## Chapter III

Figure III. 11 Proposed calculation scheme for the vector rotation stage.

Table III. 5 Comparison of the number of operations and functions required to perform a reference frame transformation between the proposed algorithms and state-of-the-art methods.

| Method | Type of functions | \#Add | \#Mult | \#Func |
| :---: | :---: | :---: | :---: | :---: |
| Euler angles | arctg, div, sqrt, sin, cos | 12 | 27 | 13 |
| Rodrigues' rotation formula | Arcsin, div, sqrt, sin, cos | 18 | 27 | 7 |
| Quaternions | Arcsin, div, sqrt, sin, cos | 32 | 54 | 9 |
| Proposed | sqrt, div | 13 | 25 | 4 |

## Square root algorithm

The circuit for the reference frame rotation has been implemented with both a FP and a Fixed-Point (FI) architecture. In each case, two different algorithms have been developed to perform the square root and division operations.

FP square root has been implemented by using the Taylor series expansion. Considering that the standard 32-bit floating-point coding (FP32) has been used (IEEE, 2019), the square root of a number $n$ can be expressed as:
$\sqrt{n}=\sqrt{2^{e x} \cdot \text { significand }}=2^{e x / 2} \cdot \sqrt{\text { significand }}$
where $e x$ is the exponent and significand is the significand for the FP number $n$. The significand can be approximated using the Taylor series. To keep the error below the precision of the significand $\left(2^{-23}=1.19 \times 10^{-7}\right)$, the square root function has been expanded around 11 different points using a third-order Taylor series. For the exponent, a division by two must be performed. If the exponent is an even number a right shift is performed, otherwise the exponent is decreased by 1 , right-shifted by 1 , and then multiplied by $\sqrt{2}$.

FI square root has been implemented by using the Taylor series expansion too. During GR, such operation is only used to calculate the norm of the gravity vector, $\|\vec{g}\|$, from the square of the norm of the gravity vector, $\|\vec{g}\|^{2}$. Since values are represented as a multiple of the acceleration due to gravity, the following assumption can be made:

$$
\begin{equation*}
\sqrt{\|\vec{g}\|^{2}}=\sqrt{1+\varepsilon} \tag{68}
\end{equation*}
$$

where $\varepsilon$ is the variation around the nominal value $\left\|\vec{g}_{\text {nom }}\right\|^{2}$. Based on (68), the following equality has been exploited:

$$
\begin{equation*}
\sqrt{r}=\sqrt{1+x}=\sqrt{1+x_{0}}+\frac{\left(x-x_{0}\right)}{2 \sqrt{1+x_{0}}}+\frac{\left(x-x_{0}\right)^{2}}{8 \sqrt{\left(1+x_{0}\right)^{3}}}+\frac{\left(x-x_{0}\right)^{3}}{16 \sqrt{\left(1+x_{0}\right)^{5}}} \tag{69}
\end{equation*}
$$

where $r$ is the radicand, $x$ is the variation around 1 , and $x_{0}$ is the point around which the series is calculated. In particular, the square root function has been approximated using a third-order Taylor series. To keep the error below the precision of the adopted fixed-point encoding $\left(\sigma=2^{-16}\right)$, the function has been expanded around 10 different points over the range [0.8, 6]. In Figure III. 12 the approximation error is represented. As one may notice, the range is not symmetrical about 1. In fact, for $r$ values lower than 0.8 , the curve becomes too steep, and too many points would be required to keep the error below $\sigma$. However, because of the low frequency associated with the human motion acceleration signal, the low-frequency component resulting from the filtering operation may be affected by significant fluctuations around the nominal value, based on the value of the cutoff frequency of the filter. For values $\|\vec{g}\|^{2}$ lower than 1 , this can cause to go out of the range $[0.8,6]$. To address this problem, the radicand is multiplied by 4 when its value is lower than 0.8 , then the square root operation is performed, and the result is divided by 2 . This allows expanding the range to [0.2, 6], and gives more flexibility for the use of this technique compared to the cutoff frequency of the filter. Moreover, the multiplication by 4 and the division by 2 can be easily performed through shifting operations.

## Chapter III

Figure III. 12 Approximation error in square root function computation using a third-order Taylor series expansion over the range $[0.8,6]$. The function $\sqrt{r}=\sqrt{1+x}$ has been expanded around 10 points: $\{-0.12,0,0.28$, $0.60,0.93,1.30,1.80,2.53,3.42,4.50\}$.

## Division algorithm

For both FP and FI encoding, the division algorithm is based on a conventional restoring algorithm (Richards, 1956). Nevertheless, some differences exist between the two cases. In the FP case, the restoring division algorithm needs to be applied to the significands only, and the division operation is completed by subtracting the exponents. In the FI case, the restoring algorithm can be applied to the two operands directly. However, to avoid the problem of starting the division process, the reciprocal value of the divisor is calculated through a restoring division algorithm, and the resulting value is then multiplied by the dividend.

## Sizing the wordlength

In this section, the impact of reduced precision due to the use of fixedpoint encoding is shown. The rotation algorithm has been tested on 70 datasets. Each dataset is composed of the acceleration data acquired by a LIS2DW12 tri-axial accelerometer and is associated with one of the following activities: stationary, walking, running, biking, and driving. Five different word-lengths have been investigated, which are 16-, 20-, 24-, 28-, and 32 -bits. To represent the integer part 8 bits have been used to guarantee that no overflow occurs during the GR operation, while the remaining part is associated with the fractional part.

Using MATLAB, the input data have been converted to fixed-point using the $f i$ function, while the behavior of the fixed-point arithmetic circuits has been emulated using the setfimath function. To evaluate the impact of the
reduced precision, an ANN, composed of 5 layers, has been fed with fixedpoint outputs from the vector rotation stage. The resulting predictions from the ANN have been compared with the predictions obtained using floatingpoint double-precision GR outputs (as required by the original model). In Figure III.13, the maximum error rate is shown for each activity and each word-length. The error rate experiences a very significant reduction when increasing the word-length from 16 -bits to 20 -bits and from 20 -bits to 24 bits, but this reduction starts to slow down when further increasing the number of bits. Thus, a 24 -bit fixed-point encoding has been chosen to implement the vector rotation stage. It should be noticed that this choice allows using the same number of bits both in the filtering and the vector rotation stages. This will be later exploited in the HW design, by using a sharing circuitry for the filtering and the vector rotation operations.

Figure III. 13 Maximum predictions error rate when an ANN is fed with fixed-point results from the vector rotation stage. Predictions obtained when the ANN is fed with floating-point double-precision outputs are taken as reference.

Chapter III

## Chapter IV <br> Hybrid Binary Neural Network

A new NN model has been studied to classify human activities. The model has been named Hybrid Binary Neural Network (HBN) because it exploits the low complexity of BNNs, but it uses non-binarized output activations for some layers in order to preserve accuracy compared to a 32bit FP implementation. The HBN has been built and tested in Lasagne (Lasagne, 2018), which is a lightweight library to build and train neural networks. A custom dataset and 2 public datasets have been used to train and test the HBN. The custom dataset has been created by the System Research and Application group in STMicroelectronics, Agrate Brianza, Italy. Five activities were performed during the data collection, i.e. standing, walking, running, biking, and driving. The dataset is composed of $1,443,958$ samples for training and 922,287 for testing. The public datasets that have been used are PAMAP2 and SHL, which have been described in paragraph II. 5 .

## IV. 1 Proposed HAR systems

The HBN has been used to perform the HAR task. Considering that inertial sensors usually embed both an accelerometer and a gyroscope, three possible configurations for the HAR system have been proposed and tested:

1. In the first configuration, the input comes from a 3-axis accelerometer only. Data is pre-processed using the algorithm proposed in paragraph III. 3 before being classified by the HBN. The system is represented in Figure IV.1. Pre-processing operations aim to remove the uncertainties due to the unknown orientation of the sensor.
2. In the second configuration, the input comes from a 3-axis accelerometer only, and raw data is classified by the HBN without any pre-processing operations. The system is represented in Figure IV.2. This is the solution that requires the lowest number of resources among the proposed ones.

## Chapter IV

3. In the third configuration, the input comes from a 3-axis accelerometer and a 3-axis gyroscope. No data pre-processing is performed. The system is represented in Figure IV.3. In this case, higher accuracy can be expected because more information is provided as input. However, it should be noticed that higher resources and power consumption has to be expected as well. Indeed, 6 input channels are used as input for the HBN, against the 3 input channels used in configurations 1 and 2. Also, gyroscopes usually have higher power consumption than accelerometers. As an example, the current absorption of the accelerometer in the iNEMO inertial module (STMicroelectronics, 2018), produced by STMicroelectronics, is $170 \mu \mathrm{~A}$ in high-performance mode. When using both the accelerometer and the gyroscope in high-performance mode, the current absorption increases to $550 \mu \mathrm{~A}$.
The details of each configuration are summarized in Table IV.1.

Figure IV. 1 Configuration 1 for the proposed HAR system. The input comes from a 3-axis accelerometer only. Data is pre-processed to remove the uncertainties due to the unknown orientation of the sensor. The classification is achieved by the HBN model.

Figure IV. 2 Configuration 2 for the proposed HAR system. The input comes from a 3-axis accelerometer only. No pre-processing operations are performed. The classification is achieved by the HBN model.

Figure IV. 3 Configuration 3 for the proposed HAR system. The input comes from a 3-axis accelerometer and a 3-axis gyroscope. No pre-processing operations are performed. The classification is achieved by the HBN model.

Table IV. 1 Summary of the 3 configurations for the proposed HAR systems.

| Configuration | Input | Pre-Processing |
| :---: | :---: | :---: |
| 1 | 3-axis acc | Yes |
| 2 | 3-axis acc | No |
| 3 | 3-axis acc + 3-axis gyro | No |

## IV. 2 Hybrid Binary Neural Network architecture

The HBN is a CNN composed of two CONV layers and two FC layers, having all the weights binarized, namely they can only be equal to +1 or -1 . For the layers whose output activations are binarized, the activation function is the sign function in (26). For the remaining layers, the activation function is the ReLU function in (21). The block diagram of the HBN model is shown in Figure IV.4, where 3 input channels and 5 classes are assumed. The inputs of the HBN are the components of the acceleration vector, pre-processed as shown in the following. An input window of 24 samples has been considered. Four sequential stages can be identified. The first stage is made up of a CONV layer and a normalization layer. The CONV layer applies a set of 8 filters (each one represents a channel) with length 5 on the signal, thus producing 8 different outputs per axis. In the normalization layer, each sample is scaled by a factor $p$ and a mean value $m$ is subtracted. Values for $p$ and $m$ are learned during the training phase. In the first stage, the output activations are binarized. The second stage is made up of a CONV layer and a Max-Pool layer. In this case, the input activations are composed of 8 channels that have been binarized considering that most of the operations are performed in this stage (Table IV. 2 and Table IV.3). As for the first stage, each axis is processed separately. The CONV layer applies a set of 8 filters of size $8 \times 5$, while the Max-Pooling has size $4 \times 1$. Successively the ReLU activation function is applied. The structure of the third stage is similar to the first one, but in place of the CONV layer, there is a FC layer made up of 64 neurons. Even though weights are binarized, parameters needed for this stage require most of the memory size (Table IV. 2 and Table IV.3). The last

## Chapter IV

stage of the HBN is made up of a FC layer and a SoftMax classifier. The output of this last stage represents the probability of belonging to each class, therefore the number of units of the fully connected corresponds to the number of classes considered. Thus, the number of neurons in the last layer has been modified according to the dataset used to train and test the HBN. The complexity of the HBN is summarized in Table IV. 2 and Table IV. 3 in terms of memory required to store parameters and the number of operations to be performed. In particular, data in Table IV. 2 reports the complexity of the HBN in configurations 1 and 2, when a single 3-axis accelerometer is used as input. Instead, data in Table IV. 3 reports the complexity of the HBN in configurations 3, when a 3-axis accelerometer and a 3-axis gyroscope are used as input. In the latter case, the memory required to store parameters and the number of operations per sample are is 1.75 and 1.94 times higher, respectively.

Figure IV. 4 Architecture of the exploited HBN. The "(Binarization)" label indicates where binarization occurs for the output activations. A 16-bits fixed-point format is assumed as input.

Table IV. 2 Complexity of the proposed HBN model. Data refer to configuration 1 and configuration 2, i.e. when data from a single 3-axis accelerometer are provided as input. 5 output classes are assumed.

| Layer | Output <br> shape | Parameters <br> [bytes] | Number of <br> parameters | Op. per <br> sample | Type of op. |
| :--- | :---: | :---: | :---: | :---: | :---: |

## IV. 3 Accuracy performance of the proposed HAR systems

## IV.3.1 Training settings

The 3 configurations for the proposed HAR systems have been tested to measure the accuracy in the classification of human activities. To do so, the HBN has been trained and the following training settings and hyperparameters have been used:

- Optimization method: Adam (Kingma, 2015)
- Loss function: squared hinge loss
- Number of epochs: 30
- Batch size: 100
- Learning rate: from $3 \times 10^{-3}$ to $3 \times 10^{-7}$

The mathematical expression of the squared hinge loss is the following:

$$
\begin{equation*}
L(y, \hat{y})=\sum_{i=0}^{N}\left(\max \left(0,1-y_{i} \cdot \hat{y}_{i}\right)^{2}\right) \tag{70}
\end{equation*}
$$

where $\hat{y}$ is the predicted value and $y$ is either 1 or -1 . Also, the learning rate is not constant, but it decreases with a constant decay factor that is obtained by the following formula:
$l r_{-} d e c a y=\left(\frac{l r_{-} \text {end }}{l r_{-} \text {start }}\right)^{\frac{1}{\text { mum_epochs }}}$
where $l r_{-}$end is the learning rate at the end of the training process, i.e. during the last epoch, lr_start is the learning rate at the beginning of the training process, i.e. during the first epoch, and num_epochs is the number of

## Chapter IV

epochs specified for the training process. Considering the above hyperparameters, the learning rate decay is equal to 0.736 .

## IV.3.2 Accuracy on PAMAP2 dataset

The public dataset PAMAP2 (Reiss, 2012) has been used to test the proposed HAR system. The dataset is described in paragraph II.5.1 It provides data from 9 users performing 12 standard human activities. The accuracy performance has been evaluated in 2 different conditions:

1. In the first case, the accuracy of the HAR system has been tested in classifying 5 human activities (standing, walking, running, cycling, rope jumping) among the 12 activities provided in PAMAP2.
2. In the second case, the accuracy of the HAR system has been evaluated in classifying all 12 activities provided by the PAMAP2 dataset.
In both cases, $k$-fold cross-validation with $k=5$ has been performed to measure accuracy. Also, 3 different sensor positions can be chosen in the PAMAP2 dataset, and 2 different accelerometer ranges can be selected. In total 6 different combinations of sensor positions and accelerometer ranges have been considered for both case 1 and case 2 . These are specified in Table IV. 4.

Table IV. 4 Possible combinations between sensor position and accelerometer range in the PAMAP2 dataset.

| ID | Sensor Position | Acc range |
| :--- | :---: | :---: |
| ankle16g | ankle | $\pm 16 \mathrm{~g}$ |
| ankle6g | ankle | $\pm 6 \mathrm{~g}$ |
| hand16g | hand | $\pm 16 \mathrm{~g}$ |
| hand6g | hand | $\pm 6 \mathrm{~g}$ |
| chest16g | chest | $\pm 16 \mathrm{~g}$ |
| chest6g | chest | $\pm 6 \mathrm{~g}$ |

## Accuracy Performance on 5 classes

In Figure IV.5, the accuracy performance of the proposed HAR system is graphed for each combination listed in Table IV. 4 and for each configuration of the proposed HAR system. The numerical values are provided in Table IV.5. Results show that the best accuracy is always obtained with configuration 3 when both accelerometer and gyroscope are used. The highest accuracy, $99.94 \%$, is obtained for the chest $6 g$ combination. By comparing configurations 1 and 2 , it turns out that pre-processing operations allow increasing the accuracy at the ankle and hand positions, whereas no
improvement is obtained at the chest position. This behavior can be explained by considering that no rotational movements are experienced by the sensor when it is located at the chest of the user, whereas they are present at the hand and ankle locations.

## Accuracy Performance on 12 classes

The same evaluation performed on 5 classes has been repeated on all 12 classes provided in the PAMAP2 dataset. The accuracy performance is graphed in Figure IV.6, whereas the numerical values of the accuracy are provided in Table IV.6. In this case, only configurations 2 and 3 have been considered because the preprocessing operations in configuration 1 would have made indistinguishable some activities. In particular, when transforming the acceleration measurements from the DCS to the WCS, activities such as lying, sitting, and standing would have been indistinguishable. Even in this case, the best accuracy is always obtained with configuration 3 , and the highest accuracy, $70.99 \%$, is obtained for the chest6g combination.

## IV.3.3 Accuracy Performance on the SHL dataset

The public dataset SHL (Ciliberto, 2017) has been also used to test the proposed HAR system. The dataset is described in paragraph II.5.2. It was by 3 users engaging in 8 different modes of transportation. The accuracy performance has been evaluated in 2 different conditions:

1. In the first case, the accuracy of the HAR system has been tested in classifying 5 modes (car, walk, run, bike, still) among the 8 ones provided in SHL.
2. In the second case, the accuracy of the HAR system has been evaluated in classifying all 8 transportation modes provided by the SHL dataset.
In both cases, $k$-fold cross-validation with $k=5$ has been performed to measure accuracy. Also, 4 different sensor positions can be chosen in the SHL dataset, i.e. Bag, Hand, Hips, and Torso.

## Accuracy Performance on 5 classes

In Figure IV.7, the accuracy performance of the proposed HAR system is graphed for each sensor position and each configuration of the proposed HAR system. The numerical values of accuracy are provided in Table IV.7. As for the PAMAP2 dataset, results show that the best accuracy is always obtained with configuration 3, except for the Torso position where configuration 2 gives slightly higher accuracy. However, the difference is only 0.21 percentage points, which can be attributed to random variations. To prove that, the capacity of the proposed HAR system has been measured.

## Chapter IV

For this experiment, the dataset has not been split between the training and testing dataset, whereas the same data has been used both during training and testing. This allows getting the maximum achievable accuracy because the system is tested on the same data used for training.

Results are graphed in Figure IV. 8 and they show again that the best configuration in terms of accuracy is always configuration 3 . The numerical values of capacity are provided in Table IV.8. The highest values of accuracy and capacity are $98.73 \%$ and $98.82 \%$, respectively, and they are both obtained with configuration 3 at the Bag position. By comparing configurations 1 and 2, it turns out that pre-processing operations allow increasing the accuracy only at the Hand position. This result reinforces the argument that pre-processing operations are not useful when no rotational movements are experienced by the sensor, as it happens for the Bag, Hips, and Torso positions.

## Accuracy Performance on 8 classes

The same evaluation performed on 5 classes has been repeated on all 8 classes provided in the SHL dataset. The accuracy performance is graphed in Figure IV.9, whereas the numerical values of the accuracy are provided in Table IV.9. Even in this case, the capacity of the proposed HAR system has been measured as well. The capacity is graphed in Figure IV.10, whereas the numerical values are provided in Table IV.10. The highest values of accuracy and capacity are $97.33 \%$ and $97.50 \%$, respectively, and they are both obtained with configuration 3 at the Bag position, as for the case of 5 classes.

## IV.3.4 Accuracy on custom dataset

The proposed HAR system has been also tested on a custom dataset. Data were collected with a 3 -axis accelerometer. Five activities were performed during the data collection, i.e. standing, walking, running, biking, and driving. The dataset is composed of $1,443,958$ samples for training and 922,287 for testing. In this case, only configurations 1 and 2 have been tested, due to the absence of data from a 3 -axis gyroscope. Also, $k$-fold cross validation has not been performed because data were already packed in .pkl files. The results show an accuracy of $97.46 \%$ for configuration 1, while the accuracy of $93.60 \%$ is achieved with configuration 2 .

Figure IV. 5 Graph of the accuracy of the 3 configurations for the proposed HAR system on 5 classes from the PAMAP2 dataset. All combinations of sensor position and accelerometer range are considered.

Table IV. 5 Numerical values of the accuracy of the 3 configurations for the proposed HAR system on 5 classes from the PAMAP2 dataset. All combinations of sensor position and accelerometer range are considered.

| Combination | Conf 1 | Conf 2 | Conf 3 |
| :--- | :---: | :---: | :---: |
| ankle16g | $98.33 \%$ | $97.78 \%$ | $99.56 \%$ |
| ankle6g | $99.64 \%$ | $98.46 \%$ | $99.55 \%$ |
| hand16g | $99.57 \%$ | $97.87 \%$ | $99.78 \%$ |
| hand6g | $99.52 \%$ | $98.78 \%$ | $99.76 \%$ |
| chest16g | $96.97 \%$ | $98.42 \%$ | $99.93 \%$ |
| chest6g | $98.15 \%$ | $98.32 \%$ | $99.94 \%$ |

## Chapter V HW accelerator design

During the last part of this research activity, a custom HW accelerator for the HAR system proposed in paragraph IV. 1 has been designed. The architecture has been designed to be compliant with the specifications of an ultra-low power smart sensor. Thus, ultra-low power consumption and a small footprint are mandatory. A custom HW architecture has been designed to implement the reference frame transformation from the DCS to the WCS, i.e. the pre-processing operations required in the system represented in Figure IV.1. This custom HW architecture is the pre-processing module in the overall HW accelerator. It should be noticed that the pre-processing module allows implementing both the filtering stage and the vector rotation stage. Then, a custom HW architecture has been also designed to execute the HBN model, which is the HBN accelerator.

All the HW architectures that have been designed have been both implemented with FPGA and synthesized with CMOS standard cells. A Xilinx Artix-7 (xc7a35tfgg484-1) FPGA (Xilinx, 2020) has been used for the FPGA implementation, and the Xilinx Vivado toolchain has been used to design and simulate the circuit. The Cadence toolchain has been used to design and simulate the CMOS standard cells implementation: Cadence Genus has been used to synthesize the design, Cadence NCSIM has been used to simulate the design, and Cadence Joules has been used to estimate the power consumption at the RTL level. To increase the accuracy of the power estimation, Value Change Dump (VCD) files have been extracted from post-synthesis simulations using Standard Delay Format (SDF) files.

Also, a FPGA-based demo board has been developed to prove the realtime operation of the proposed HAR system.

## V. 1 Pre-processing module

The pre-processing module is the custom HW architecture that executes the pre-processing operations. As explained in paragraph III.3, the preprocessing operations can be divided into two stages: the filtering stage and

## Chapter V

the vector rotation stage. Considering the very low sampling frequency associated with HAR systems, the main contribution to the power consumption is given by leakage power. Thus, the main criterion in the design of the HW circuitry has been to reduce the number of required resources, i.e. the area of the circuit. In the following, it will be shown that a shared reconfigurable architecture has been designed to execute both the filtering stage and the vector rotation stage.

## V.1.1 Gravity Rotation Unit

## HW module description

The architecture designed to implement the reference frame transformation is schematized in Figure V.1. The core is the Gravity Rotation Unit (GRU), which implements the repetition pattern described in paragraph III.3.2. An iterative structure has been implemented, which allows reducing the mapped resources and, hence, the overall power density, at the cost of multicycle processing. This approach makes use of the reduced bandwidth of typical human activities, which allows lowering timing and keeping power consumption low. Furthermore, all the partial results are stored in distributed registers, avoiding the energy-consuming write/read operations associated with SRAMs or external DRAMs, typically required in general-purpose microcontrollers and processors. Inputs to the GRU, namely the vectors $\left(g_{x}, g_{y}, g_{z}, v_{x}, v_{y}, v_{z}\right)$ or the outputs fed back through a bank of registers, are simply selected by a MUX. Each output feeds a shift register made up of 4 Flip-Flops (FFs), which allows storing partial results from previous cycles. Outputs from each register, in turn, are provided as inputs to the MUX. Each new input requires a certain number of cycles to be processed. Since an onerous pipeline structure has been avoided, a 6 -bit counter is used to manage the MUX. Three divisors complete the normalization step (66), while the initial square root circuitry is embedded into the GRU module, schematized in Figure V.2. The GRU is composed of three multipliers operating in parallel, two cascaded adder/subtractors, and three multiplexers. The module operates on the inputs $i 1-i 6$ and provides three outputs at each cycle, which can be alternatively taken from the outputs of multipliers and adders. During the processing, the six inputs assume the values in Table V.1, which refer to the equations presented in paragraph III.3. In the table, "ox_y" indicates the output ox (with $x=\{1,2,3\}$ ) taken $y$ cycles before the current one (with $y=\{1,2,3,4\}$ ). The operations of GRU require 18 iterations, 8 of which ( 3 to 10 ) are devoted to the square root for the norm calculation.

## Differences between FP and FI implementations

Despite Figure V. 1 and Figure V. 2 describe well the architecture for both the FP case and the FI case, some differences must be taken into account.

In the FP architecture, the multipliers are 32-bit Booth multipliers, while the adders are 32-bit carry-ripple adders. The final divisions require 27 additional cycles, leading to 45 overall cycles to complete the processing. Therefore, if the accelerometer frequency is set to $f \mathrm{~s}=25 \mathrm{~Hz}$, the lower limit for the clock frequency is $45 \times f \mathrm{~s}=45 \times 25 \mathrm{~Hz}=1125 \mathrm{~Hz}$.

In the FI architecture, the multipliers are 24 -bit Booth multipliers, while the adders are 24-bit carry ripple adders. This choice is justified by the wordlength sizing described in paragraph III.3.2. In this case, to further reduce the area occupation, and, hence, the power dissipation due to leakage, the multipliers have been implemented in an iterative fashion. Each multiplier is made up of a Booth cell only, and 12 cycles are required to carry out the multiplication. To synchronize the multipliers with the operation of the whole architecture, a dedicated clock signal (clk_mult) has been used, whose frequency is 12 times higher than the frequency of the general clock signal (clk). The final divisions require 23 additional cycles, leading to 41 overall cycles to complete the processing. Therefore, if the accelerometer frequency is set to $f_{s}=25 \mathrm{~Hz}$, the lower limit for the main clock frequency is $41 \times \mathrm{fs}=41 \times 25 \mathrm{~Hz}=1025 \mathrm{~Hz}$. Then, the lower limit for the frequency of the clk_mult signal is 12.3 kHz .

## Chapter V

Figure V. 1 Block diagram of the HW module used to execute the reference frame transformation from DCS to WCS. The core of the HW module is the Gravity Rotation Unit (GRU).

Figure V. 2 Block diagram of the Gravity Rotation Unit. The module is made up of 3 multipliers, 2 adders, and MUXs to properly manage the dataflow.

## Results

The proposed design has been implemented on the Xilinx xc7z020clg484-1 FPGA to test its functionalities and synthesized in TSMC 65 nm CMOS technology for both the FP case and the FI case. The main results are reported in Table V.2. The absence of comparisons with alternative designs is justified by the absence in the literature of HW designs with the same characteristics of low power consumption and reduced occupied area.

In the FP case, most of the resources ( $6460 \mathrm{LUTs}=75.2 \%$ of the overall resources) are required by the GRU. In turn, each multiplier occupies about $20 \%$ of the GRU. The remaining 2134 LUTs are mainly used by the divisors. Results from the synthesis in 65 nm CMOS technology report an area occupation of $0.05 \mathrm{~mm}^{2}$ and power consumption of about $1.7 \mu \mathrm{~W}$ when the clock frequency is set to 1.125 kHz and clock gating is enabled. Thus, energy per cycle is 1.5 nJ , while energy per GR operation is 68 nJ . For low
power aims, technology is the limiting factor since about $60 \%$ of the power consumption is due to leakages, although low-leakage libraries and devices with a High Voltage Threshold (HVT) have been used. Output values from the implemented design have been compared with the expected results from the test model. The comparison reveals a maximum error of $4 \times 10^{-6}$ in the significand representation. This little discrepancy is justified by the propagation of the FP32 representation error during the 45 clock cycles needed to complete the elaboration of a sample. To verify the irrelevancy of this error, the neural network has been tested using the output values from the circuits. The test has shown that results perfectly match up with the predictions obtained in the test model.

Table V. 2 Comparison between FP and FI implementation of the HW architecture to execute the reference frame rotation operation. Results from both the FPGA implementation and the CMOS standard cell synthesis are reported.

|  | Floating-Point (32-bit) |  | Fixed-Point (24-bit) |  |
| :--- | :---: | :---: | :---: | :---: |
|  | FPGA | CMOS 65 nm | FPGA | CMOS 65 nm |
| Dynamic <br> power [mW] | $<1$ | $1.7 \cdot 10^{-3}$ | $<1$ | $0.89 \cdot 10^{-3}$ |
| Static power <br> [mW] | 104 | $0.68 \cdot 10^{-3}$ | 104 | $0.26 \cdot 10^{-3}$ |
| Total power | $\cong 104$ | $1.02 \cdot 10^{-3}$ | $\cong 104$ | $0.63 \cdot 10^{-3}$ |
| [mW] | 8594 | - | 2760 | - |
| \#LUTs | 1285 | - | 1305 | - |
| \#FFs | - | 0.05 | - | 0.024 |
| Area [mm ${ }^{2}$ ] | - |  |  |  |

In the FI case, a significant amount of resources is required to implement the dividers, which use about $45 \%$ of the LUTs. Despite the GRU is the core unit of the proposed accelerator, it requires $28 \%$ of the LUTs only. This is achieved thanks to the iterative implementation of the multipliers. The remaining resources are needed to implement the glue logic, i.e. the input MUX. The FPGA implementation shows that the delay associated with the critical path is 15.417 ns for clk_mult intra-clock paths, while it is 28.380 ns for $c l k$ intra-clock paths. Thus, the maximum operating frequency for the clk_mult signal is 64.86 MHz . As a consequence, the maximum operating frequency for the clk signal is 5.40 MHz , which is much higher than the specified lower limit. Results from the synthesis in 65 nm CMOS technology report an area occupation of $0.024 \mathrm{~mm}^{2}$ and a dissipated power of about $0.89 \mu \mathrm{~W}$ when the general clock (clk) frequency is set to 1.025 kHz . Thus, the energy per clock cycle is 0.87 nJ , while energy per GR operation is 35.6 nJ . For low power aims, technology is the limiting factor since more

## Chapter V

than $70 \%$ of the dissipated power is due to leakages, although low-leakage libraries and devices with a HVT have been used. The results show a $2 \times$ reduction compared to the FP implementation both in area occupation and power consumption, with minimum impact on the overall accuracy of the system

## V.1.2 Filter stage circuitry

## Coupled-All pass filter realization

As shown in Figure III.6, a highly regular structure is obtained when allpass filters are realized through the two-pair extraction approach. This allows obtaining an iterative implementation of the filter, in which the same fundamental cell (see Figure III.5) is re-used a number of times equal to the order of the filter. Based on this method, a Coupled All-Pass filter also can be implemented in an iterative fashion. Considering what has been explained in paragraph III.3.1, the same fundamental cell can be used to emulate $A_{1}(z)$ first and then $A_{2}(z)$. Considering Figure V.3, first, the cells I, II, and III of the filter $A_{1}(z)$, and then the cells IV and V of the filter $A_{2}(z)$ are emulated using the fundamental all-pass cell. Lastly, cell VI is emulated using the same fundamental cell in which only the adder is used. How the all-pass fundamental cell must be used is described by the following equations:
$Y_{1}=V_{1}+z^{-1} X_{2}$
$Y_{2}=X_{1}+V_{1}$
$V_{1}=k_{m}\left(X_{1}-z^{-1} X_{2}\right)$

Figure V. 3 Realization of the filter using a Coupled All-Pass structure and iterating on an All-pass fundamental cell. The latter is detailed in the dark black box in the upper right corner of the figure. Each used cell is identified with a Roman numeral.

## Re-using the Gravity Rotation Unit resources

Noting that $V_{1}$ is required for the computation of both $Y_{1}$ and $Y_{2}$, the circuitry for its calculation is implemented once but its result is used to calculate $Y_{1}$ and $Y_{2}$ in two consecutive cycles. The scheme representing the computation of $V_{1}$ is represented in Figure V.4, while the scheme for the computation of $Y_{1}$ and $Y_{2}$ is represented in Figure V.5. In both cases, the scheme can be realized using part of the GRU described earlier. In the end, the whole fundamental cell can be realized using part of the circuitry of the GRU, as shown in Figure V.6.

Having used an iterative implementation, 12 cycles are needed to process a single sample from the accelerometer. However, the accelerometer provides three outputs in parallel, each related to a different axis. As a consequence, in order to process the three samples, 36 total cycles are needed. If the sampling frequency of the 3 -axis accelerometer is 25 Hz , the minimum allowable clock frequency for the filter is $36 \times 25 \mathrm{~Hz}$, which is 900 Hz .

Figure V. 4 (a) Scheme for the calculation of $V_{1}$ and (b) part of the GRU needed to implement the scheme.

Figure V. 5 (a) Scheme for the calculation of $Y_{1}, Y_{2}$ and (b) part of the GRU needed to implement the scheme.

Figure V. 6 (a) Fundamental all-pass cell, (b) HW implementation for its realization, and (c) the corresponding part of the GRU needed to implement the scheme.

## V.1.3 Pre-processing module architecture

As shown in the previous paragraph, the filtering stage and the vector rotation stage can be implemented using a shared circuitry. This allows obtaining a reconfigurable architecture, which can operate both in "filtering mode" and in "GR mode". The reconfigurability is obtained through multiplexers (MUXs) that allow proper routing of the signals. To minimize the power consumption of the architecture, FI 24-bit coding has been used. The scheme of the designed reconfigurable architecture is shown in Figure V.7, where the MUXs in black are the ones that allow switching from one mode to another. Using this scheme, 36 cycles are required to filter the input samples from the ADC of the sensor ("from sensor" in the figure). Then, the GR operation requires 34 cycles, where the last 18 cycles are needed to perform the normalizations in (66). Considering that the divisions are implemented through a dedicated circuitry, only the first 16 cycles of the GR operation need to be serialized with the 36 cycles of the filtering operation, while the remaining 18 cycles can be run in parallel. Thus, the total number of cycles required to perform the whole pre-processing pipe is 52 . If the sampling frequency of the accelerometer is 25 Hz , the minimum allowable clock frequency for the design in Figure V. 7 is $25 \times 52 \mathrm{~Hz}=1.3 \mathrm{kHz}$ $(12 \times 1.3 \mathrm{kHz}=15.6 \mathrm{kHz}$ for the clk_mult signal).

The design in Figure V. 7 has been synthesized using Cadence in TSMC 65 nm CMOS technology. The results are summarized in Table V.3. The power consumption has been estimated at 15.6 kHz .

Figure V. 7 Block diagram of the HW architecture which implements the overall preprocessing module.

Table V. 3 Synthesis results of the pre-processing module.

| Technology | Dynamic <br> power $[\mathrm{uW}]$ | Leakage <br> power [uW] | Total power <br> $[\mathrm{uW}]$ | Area <br> $\left[\mathrm{mm}^{2}\right]$ |
| :---: | :---: | :---: | :---: | :---: |
| 65 nm HVT | 0.45 | 0.81 | 1.26 | 0.030 |

## V. 2 HBN accelerator

A custom HW accelerator to execute the HBN model proposed in paragraph IV. 2 has been designed as well. Generally, Two aspects are critical in the HW implementation of ANNs: the large number of arithmetic operators and the allocation of a large amount of memory for storing weights and partial results, as well as the power dissipation related to the numerous memory accesses (Sze, 2017). In the proposed implementation, weight binarization has reduced the MAC operations to simple ADD/SUB operations, namely each CONV layer calculates the following quantities:

$$
\begin{equation*}
\sum_{i=1}^{N} w_{i} x_{i}+b= \pm x_{1} \pm x_{2} \pm \ldots \pm x_{N}+b \tag{72}
\end{equation*}
$$

where $w_{i}$ and $x_{i}$ are the weights and the inputs to a certain neuron, respectively, and $b$ is the bias. Since the energy cost of data read/write operations from off-chip memories can be up to $200 \times$ higher than on-chip data transfer (Sze, 2017), an effort has been done to use only on-chip memories.

## V.2.1 Architecture of the HBN accelerator

Two designs of the HNN accelerator are proposed. The first one is the FIFO-based design, where memories have been implemented by using

## Chapter V

distributed FIFOs and RAM has been completely avoided. A second version is the RAM-based design, which uses RAM to store weights and biases, while FIFOs continue to be used to store the output activations. The choice to present both solutions derive from the need to find different optimal area/power trade-off in different utilization scenarios. Auxiliary circuitry of sensors, indeed, are equipped with a very limited amount of RAM, which could be insufficient for the HAR operations, and compel to use FIFOs. In turn, FIFOs permit higher operation frequencies than RAM, and the associated dynamic power scale up with a lower slope than RAM. This makes FIFOs convenient for higher frequencies applications. On the contrary, RAM could be a convenient choice for target platforms such as FPGA, which could advantage of distributed memories and the lower power dissipation for data transfers, due to the locality of data. The block diagram of both HBN designs is shown in Figure V.8. The architecture exploits 3 cores since this is the minimum number of cores that can process in parallel the 3 components of the pre-processed acceleration. In Figure V. 9 and Figure V.11, the architectures of the cores of the FIFO-based and the RAMbased HNN accelerator are detailed. Thanks to weight binarization, the processing element (PE) is a 3-levels adder tree that uses 16-bits FI arithmetic in both cases. The first level of the adder tree is made up of 3 adders so that a dot product between vectors of length 5 can be performed in one cycle, and a bias or a result from the previous cycle can be summed up as well.

Figure V. 8 Block diagram of the proposed HBN accelerator. The RAM module is present in the RAM-based design only. The structure of the cores is different for the two versions.

Another aspect of the proposed design is scalability. If higher throughput were required by the target application, the number of cores can be increased with a very low design effort. Indeed, the strategy of storing the model weights locally in each core mitigates the bandwidth-related issues that normally would arise when scaling up the design (Chen, 2019). Thus, we can expect that the performance varies linearly with the number of cores. For
example, by doubling the number of cores we can expect a doubling of power, area, and throughput.

## Architecture of the cores in the FIFO-based HBN accelerator

The block diagram of each core in the FIFO-based HBN accelerator is shown in Figure V. 9 In the FIFO-based design, each core embeds 800 bytes of FIFO memories in which weights, biases, and partial results are stored. Each core locally stores all the parameters needed to run the model. Also, output activations from CONV layers are locally reused in each core. Thus, the design takes advantage of a "flattened" memory hierarchy, where there is no need to execute high-cost access operations to higher levels in a memory hierarchy. To make this possible, FIFOs must be initialized during the system start-up by an external data stream. Successively, FIFOs work as a circular buffer, carefully managed by a Control Unit (CU). In particular, in the design in Figure V.9, the "FIFO_w" structures store the weights of the model, whereas "the FIFO_b" structures store the biases. The structure of the circular FIFOs is represented in Figure V. 10 for both the "FIFO_w" and the "FIFO_b" structures. At the startup of the system, the CU sets the LDP signal to 1 so that FIFOs are loaded with the parameters of the model by an external stream of data. During the normal operation of the systems, the CU sets the LDP signal to 0 , so that, each time that a parameter is read and used, it is sent back to the first element of the FIFO. By doing so, there is no need to access a higher memory hierarchy level to re-load the parameters.

As shown in Figure V.9, two different "FIFO_w" and "FIFO_b" modules are needed in each core and used when the circuit implements a CONV layer or a FC layer, respectively. Indeed, CONV layers must be processed 16 times to get new input for the FC layers. Thus, considering that in FIFO structures we cannot have random accesses to the memory locations, we should have had to swipe all the weights of the CONV and the FC layers even when the latter would have not been useful. This would have been a drawback for the design because the number of weights of the FC layers requires $77 \%$ of the total memory required to store the network parameters, as reported in Table IV.2. In particular, considering that each weight in the HBN is represented by a single bit and that each CONV layer has a filter with dimension proportional to $5(5$ or $5 \times 8)$, FIFOs for CONV layers have dimensions $80 \times 5$ bits, which corresponds to 50 bytes, while those for FC layers are $608 \times 5$ bits, which corresponds to 380 bytes. The same applies to "FIFO_b" but, considering that biases are coded with FI 16-bits, FIFOs require $16 \times 16$ bits ( 32 bytes) and $64 \times 16$ bits ( 128 bytes), respectively. "FIFO_o" stores the output activations of each layer. Each one of the above output FIFO is divided into up to 5 blocks, in order to provide up to 5 different output activations in parallel to the PE, designed to perform a dot product between vectors of length 5 in one cycle. In Figure V.9, the 3 "FIFO_o" memories store the output activations of the first stage, the second

## Chapter V

CONV layer and the Max-Pool layer, respectively. Each axis is processed separately in CONV layers, thus the memory for the output activations is locally associated with each core. As shown in Figure V.8, a unique external FIFO memory is also used to store the output activations of the first FC layer, since in this case, all the input activations from the previous layer cannot be separated. Considering that the scheme in Figure V. 8 iteratively implements all the layers of the HBN , the complex signal routing is managed by the devoted CU, which in turn has been implemented with a Finite State Machine (FSM) having a state for each layer.

Figure V. 9 Block diagram of a core in the FIFO-based design. In this case, weights and biases are stored in FIFO memories locally. FIFO_w are the FIFOs where weights are stored, whereas FIFO_b are the FIFOs where biases are stored. Output activations from CONV layers are stored in FIFO_o and are re-used locally in each core.

Figure V. 10 Detail about the management of the circular FIFOs. At the startup of the system, the CU sets the LDP signal to 1, and FIFOs are loaded with parameters by an external stream of data. During normal operations, the $C U$ sets the $L D P$ signal to 0 so that each parameter is sent back to the first element of the FIFO after having been used.

## Architecture of the core in the RAM-based HBN accelerator

The block diagram of each core in the RAM-based HBN accelerator is shown in Figure V.11. In the RAM-based design, a RAM has been instantiated to store weights and biases in place of FIFOs. The RAM is external to the core, as represented in Figure V.8. This choice is advantageous in terms of power dissipation since it avoids the data shifts that FIFOs do at each read operation, although the highest advantage is obtained with the availability of on-chip distributed RAM typical of FPGAs. The cores of the RAM-based HNN accelerator in Figure V. 11 have a similar structure to the FIFO-based ones, but a RAM module of $31 \times 696$ bits, which corresponds to 2.63 KB , reduces the FIFOs dimensions to 200 bytes. The most significant 15 bits of each word of the RAM are used to store weights, therefore again each core receives 5 binarized weights at each cycle. The remaining 16 bits are used for the biases. The proposed architecture has been prototyped with a Xilinx Artix-7 FPGA and, for ease of comparison also with standard cells (std_cells) implementation. In the latter case, a larger SRAM of $32 \times 704$ bits has been instantiated due to the limitations of the memory compiler.

Figure V. 11 Block diagram of a core in the FIFO-based design. In this case, weights and biases are stored in a RAM, which is external and shared by each core. Output activations from CONV layers are stored in FIFO_o and are re-used locally in each core.

## V.2.2 Architecture of the processing element

The Processing Element (PE) is made up of a 3-levels 16-bits fixed-point adder-tree and the circuitry to implement the activation functions (sign function (26) and ReLU (21)).

## Chapter V

## Adder Tree

Thanks to binarization multipliers are not required to process the layers in the HBN. In layers where inputs and weights are both binarized, a XNORpopcount circuitry could have been used. However, this would have been an additional circuitry, which would have required additional resources and, hence, power. Thus, even for these layers, the processing is performed in the PE by using the adder tree. Nevertheless, it must be considered that the sign of operand changes when the weight is -1 . This has been taken into account by using the circuitry in Figure V. 12 for the implementation of the adders in the first level of the adder tree. The truth table for the signals $S_{-} A, s_{-} S, C_{-} i n$, and $R C$ is reported in Table V.4. Only when all the weights are -1 ( 0 in binary) the result needs a further sum up of +1 to provide the correct results. This is accomplished by propagating a carry bit $(R C)$ to the next level of the adder tree.

Figure V. 12 Circuitry for the sign management for the first level of the adder tree in the $P E$.

Table V. 4 Signals for the sign management in the adder-tree.

| Required <br> Operation <br> (weights) | $s_{-} A$ | $C_{-}$in | $s_{-} S$ | $R C$ | Result $(S)$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| $\mathrm{A}+\mathrm{B}(1,1)$ | 0 | 0 | 0 | 0 | $\mathrm{~A}+\mathrm{B}$ |
| $\mathrm{A}-\mathrm{B}(1,0)$ | 1 | 0 | 1 | 0 | $\mathrm{~A}-\mathrm{B}$ |
| $-\mathrm{A}+\mathrm{B}(0,1)$ | 1 | 1 | 0 | 0 | $-\mathrm{A}+\mathrm{B}$ |
| $-\mathrm{A}-\mathrm{B}(0,0)$ | 0 | 0 | 1 | 1 | $-\mathrm{A}-\mathrm{B}-1$ |

## Non-linearities implementation

A small circuitry has been deployed in each core to evaluate the nonlinear functions, namely the ReLU function (21) and the sign function (26). The circuitry is represented in Figure V.13. The result of both the ReLU function and the sign function (used to implement the binarization) depends on the sign of the input operand, which is the sign "AT RES". The sign is deduced by looking at the Most Significant Bit (MSB). Thus, the multiplexer "M_ReLU" implements the ReLU function by selecting between "AT_RES"
and 0 based on "MSB(AT_RES)". Instead, the multiplexer "M_BIN" implements the binarization by selecting between +1 or -1 (represented in two's complement 16 -bits fixed point coding, with an 8 -bit fractional part) based on "MSB(AT_RES)". The signal "s_NL" is then used to select the desired non-linearity, and the signal "s_RES" is used to choose if applying the selected non-linearity or not. Finally, the non-linearities are simply performed using MUXs.

Figure V. 13 Block diagram of the circuitry for the implementation of ReLU function and binarization.

## V. 3 Results

The performance of the HW accelerator, which consists of the preprocessing module and the HBN accelerator, has been measured both with FPGA and CMOS standard cells.

## V.3.1 Results from FPGA implementation

In Table V.5, the results from the FPGA implementation are summarized for both the FIFO-based and the RAM-based designs, and the proposed design has been compared to state-of-the-art works (Jafari, 2019), (Gaikwad, 2019), which are oriented to custom HW implementation. The FPGA takes advantage of the presence of RAM since the LUT utilization is reduced by about $3 \%$ compared to the FIFO-based counterpart, namely from $31.7 \%$ to $28.8 \%$ of the total number of the available LUTs on the FPGA. Analogously, the FF utilization is reduced by about $2.3 \%$ since 1017 FFs are used to store weights and biases of the HBN. The maximum clock frequency for both designs is 41 MHz , corresponding to a maximum Output Data Rate (ODR)

## Chapter V

of the sensor of 3.2 kHz However, when the ODR of the sensor is set to 25 Hz , normally used in HAR systems, considering that 12600 clock cycles are needed to process a data, the minimum clock frequency required for realtime operation is 315 kHz , indicated as the operating frequency (OpFreq) in Table V.5. At this frequency, considering that 16 input samples are required to obtain a prediction, the delay (Delay@OpFreq) is equal to $16 \times(1 / 25 \mathrm{~Hz})=640 \mathrm{~ms}$. As shown in Table V.5, the value is higher than the ones obtained by Jafari et al. (2019) and Gaikwad et al. (2019). However, this is justified by the higher operating frequencies used in those works, which is not actually required in the proposed HAR system. However, if the proposed FPGA implementation would work at its maximum frequency, the delay will decrease to 5 ms , which is lower than the one achieved by Jafari et al. (2019). The delay obtained by Gaikwad et al. (2019) is orders of magnitude lower than the one achieved by the proposed solution. However, this is justified by the execution of a simpler model that can only achieve $94.6 \%$ accuracy. In contrast, the proposed design can achieve $99.5 \%$ accuracy (this result refers to the classification of 5 classes from the PAMAP2 dataset by using configuration 1 and hand 16 g combination, Table IV.5).

To estimate the power consumption, the power tool provided by Vivado has been set up at a high level of confidence by using Switching Activity Interchange Format (SAIF) files generated from post-implementation simulations. The power estimation returns for both designs a total power consumption of 72.04 mW at the OpFreq. This is almost all composed of static power, equal to the quiescent power dissipation of the FPGA. Dynamic power is under the sensitivity of the tool, which returns a generic $<1 \mathrm{~mW}$. Therefore, for the FPGA implementation, there are no significant differences between the two designs, and the RAM-based design could be preferred since it takes advantage of the primitives of the FPGA, while LUTs and FFs can be saved for other purposes. This should be considered in the economy of the whole system both in terms of power consumption and area occupation. A lower number of resources is required by our designs, although we do not instantiate DSP modules in order to provide results that are independent of the specific target platform, and for a fair comparison with std_cell implementations. The total RAM requirement for our RAMbased design is equivalent to 1 BRAM and 0 for the FIFO-based, while Jafari et al. (2019) use a significant number of BRAMs. The power consumption has been compared at the OpFreq of each system. The proposed design shows a reduction of the power consumption of $37 \%$ and $70 \%$ compared to the one obtained by Jafari et al. (2019) and Gaikwad et al. (2019) respectively. However, to make comparisons independent from the OpFreq, the normalized dynamic power consumption has been compared, where the proposed designs achieve a reduction of $70 \%$ compared to the results obtained by Gaikwad et al. (2019).

Table V. 5 Results from FPGA implementation of the proposed HW accelerator. The HW accelerator is made up of the pre-processing module and the HBN accelerator. The results are compared with state-of-the-art solutions as well.

## V.3.2 Results from CMOS standard cells synthesis

In Table V.6, the results of synthesis with TSMC CMOS 90 nm std_cells are summarized for both the FIFO-based and the RAM-based designs and compared with the solution in the paper by Jafari et al. (2019), which only presents ASIC results. The power consumption has been estimated by extracting Value Change Dump (VCD) files from post-synthesis simulations using Standard Delay Format (SDF) files. The power consumption has been estimated using Cadence Joules. The dynamic power consumption of the RAM-based design is 2.8 times higher compared to the FIFO-based design, while the leakage power is 1.8 times lower. However, the dynamic power consumption is negligible at the OpFreq. Therefore, despite the shifting of

## Chapter V

the data in the FIFOs does not represent an issue for the dynamic power consumption, the best solution to reduce the power consumption at the considered frequencies is the RAM-based design. On the contrary, being the memory distributed in the FIFO-based design, the maximum frequency is 1.6 times higher than the one of the RAM-based design. This could be considered for applications in which a high throughput is the first specification. Moreover, to verify the scaling capabilities and the actual impact of leakages, the proposed design has been synthesized with TSMC CMOS 65 nm low-power (LP) high-voltage-threshold (HVT). The HVT feature allows to strongly reduce the leakage power, at the cost of reduced speed. The results are reported in Table V.6. Unfortunately, the lack of a memory compiler for the 65 nm technology prevented the possibility to synthesize a RAM-based design with the more shrunk technology. Results show that the power consumption is only $6.3 \mu \mathrm{~W}$ at the OpFreq, which is 3 orders of magnitude lower than the above results. Despite this, $86 \%$ of the total power is leakage power. The overall area occupation is $0.20 \mathrm{~mm}^{2}$. A detail of the various components of the design is shown in Figure V. 14 and Figure V.15. In Figure V.14, it is shown that most of the area is required for the HNN accelerator module. In particular, each core occupies $26 \%$ of the architecture, whereas the pre-processing module occupies $16 \%$ of the total area. The remaining area is mainly used for the external FIFO (see Figure V.8), the SIPO, and the CU. Also, in Figure V. 15 the breakdown of the various modules in each core is shown. $96.9 \%$ of the area occupation in each core is due to FIFO memories, and only the remaining $3.1 \%$ is required to implement the PE. In fact, thanks to weight binarization, the PE has been implemented avoiding multipliers, whose implementation requires large and power-hungry circuits. In Figure V. 14 and Figure V.15, also a breakdown of the power consumption has been reported. Considering that power dissipation is mostly due to leakages, the power consumption breakdown exactly follows the one of the area occupation. In Table V. 6 the proposed design has also been compared to one proposed by Jafari et al. (2019). To have a fair comparison of power consumption, we have considered results at the same throughput. In the work of Jafari et al. (2019) a throughput of 67 label/s is achieved at a clock frequency of 100 MHz . In the proposed solution, 202 k clock cycles are required to produce a label. Thus, a lower clock frequency of $(67 \times 202 \mathrm{k}) \mathrm{Hz}=13.5 \mathrm{MHz}$ is required to have a throughput of 67 label/s. At this frequency, the FIFO-based design and the RAM-based design dissipate 2.54 mW and 1.52 mW , which corresponds to a reduction of 7.3 times and 12.2 times respectively compared to the power consumption obtained by Jafari et al. (2019). The delay required to produce a label and the area occupation of the proposed designs are almost the same as the one obtained by Jafari et al. (2019). The maximum frequency achieved by Jafari et al. (2019) is 5.4 times higher and 8.8 times higher than the FIFO-based design and the RAM-based design, respectively. Despite
this, the proposed design is able to provide a 1.4 times higher throughput in the case of the FIFO-based design.

It is interesting to note that the proposed design is not just competitive in terms of total power consumption, but in terms of the dynamic one. Indeed, the dynamic power consumption is up to 42 times lower than the one achieved by Jafari et al. (2019). This suggests that the proposed design might be reused for other applications as well, where higher throughput is required.

Table V. 6 Results from CMOS standard cell synthesis of the proposed HW accelerator. The HW accelerator is made up of the pre-processing module and the HBN accelerator. The results are compared with a state-of-the-art solution as well.

## V. 4 FPGA-based demo board

To prove the real-time operation of the proposed HW accelerator, this has been deployed on an Artix-7 FPGA, and a FPGA-based demo board has been realized. The HAR system prototype is shown in Figure V.16. A small Digilent CMOD A7-35T has been used to implement the entire circuitry, while the X-NUCLEO-IKS01A1 (STMicroelectonics, 2015), which mounts the LSM6DSO IMU (STMicroelectronics, 2018), is used as the 3-axis
accelerometer. The STM32F411RE microcontroller is used to manage the data transfer between IMU and FPGA and to display the processed results. The internal 12 MHz clock of the FPGA board has been used to synchronize the HW accelerator, while the microcontrollers used their own clock. Thus, an asynchronous handshake protocol has been implemented with the microcontroller to manage the data transfer between the FPGA-board and the sensor. A dedicated CU has been implemented on the FPGA side to manage the signals used to implement the data transfer. Also, the available pins on the FPGA board were not enough to allow the transfer of all data at the same time. Indeed, the proposed design is fed with data input from the 3axis accelerator, which sums up to $3 \times 16$ bits $=48$ bits. The output of the HW accelerator consists of $3 \times 16$ bits $=48$ bits because each core provides a 16 bit output. Also, additional pins are required for the implementation of the handshake protocol, which in turn sum up to the 96 pins required for input and output data. Thus, an input buffer and an output buffer have been designed and implemented with the FPGA. The microcontroller sends the input data by packing it 4-bits at once, which are progressively stored in the input buffer on the FPGA. When the input buffer is full, data starts to be elaborated by the HW accelerator. The results of the data processing are stored in the output buffer, where they are packed 4-bits at once and sent to the microcontroller. Thus, only 8 bits are required for the input and output data.

Measurements on the CMOD board return a maximum current of about 100 mA in both cases, which is increased by the additional components of the board.

Chapter V

Figure V. 16 FPGA-based demo board. The scores for each one of the 5 classes and the consequent classification are printed to video in real-time.

## Conclusions

In this work, an ultra-low power HAR system has been proposed. The design has been carried out starting from the model to its HW implementation. IS-HAR has been selected as a case study, where the input data comes from inertial sensors.

A custom HW-friendly algorithm has been developed to solve the deviceorientation problem in 3-axis accelerometers. The algorithm has been used as a possible pre-processing stage in the proposed system. The proposed solution allows implementing filtering and vector rotation with a lower number of arithmetic operators, avoiding complex trigonometric functions, and reducing the number of normalization. The algorithm has been implemented with Fixed-Point coding to reduce the number of required resources. The word-length has been sized to obtain an optimal tradeoff between the number of bits and precision, resulting in a 24-bit Fixed-Point coding, where the 8 MSBs are the integer part.

Also, a new HBN model has been proposed to achieve the classification of human activities. The HBN exploits the advantages of BNNs, but it brings an improvement in terms of accuracy without affecting the size of the model. Three different configurations have been proposed for the HAR system, based on the types of input sensors and the presence of pre-processing operations. The accuracy of the system has been measured for each configuration, where the HBN has been trained with data from 2 public datasets and 1 custom dataset. The results show an accuracy of up to $99 \%$ in classifying 5 human activities. The pre-processing operations bring an advantage in terms of accuracy only when the sensor is located at parts of the body that are subject to relevant rotational movements, such as hand and ankle.

A custom HW accelerator has been designed to implement both the preprocessing operations and the HBN model. A pre-processing module has been designed to implement the pre-processing operations. The architecture can be configured to perform either filtering operations or vector rotation operations. Then, the HBN accelerator has been designed to execute the HBN model. It is made up of 3 cores, each one processing one axis of the sensor individually. Two different versions of the design have been
investigated. The first version is the FIFO-based design, where weights and biases are stored in FIFOs that are local to each core. The second version is the RAM-based design, where weights and biases are stored in a shared RAM. The results show that the RAM-based design allows achieving lower power consumption but at the cost of a lower maximum frequency. The proposed design has been both synthesized with CMOS standard cells and implemented with FPGA. The results from synthesis with TSMC CMOS 65 nm LP-HVT standard cells show a power consumption of only $6.3 \mu \mathrm{~W}$, which is orders of magnitude lower than the custom HW implementations proposed in the literature. Also, the design has been implemented with TSMC CMOS 90 nm GP standard cells, and also in this case the power consumption is up to 12 times lower than state-of-the-art solutions.

The proposed HAR system has been also deployed on FPGA in order to realize a demo board. The demo board has allowed showing the real-time operation of the system.

In conclusion, during the Ph.D. project, the combination of reducedprecision NN models and custom HW design has been widely investigated. The results show that this allows integrating the classification stage in the sensor node, thanks to a low area occupation and power consumption in the order of tens of $\mu \mathrm{W}$. Also, some pre-processing features can be integrated as well with low impact on the system performance. However, the advantage introduced by the pre-processing operations should be assessed based on the sensor position. Thus, the results from this Ph.D. project can be a starting point for the industrial development of efficient AI-based edge computing devices.

Considering that the maximum frequency of the proposed system is far higher than the operating frequency, future works might aim to extend the proposed design to other applications that require higher throughputs, such as anomaly detection for industrial machines. Even in this case, inertial sensors are used to sample data, but the sampling frequency is in the range of tens of kHz rather than tens of Hz .

## Appendix A Confusion Matrixes for the HBN

In this section, the confusion matrixes of the HBN model for all the results presented in paragraphs IV.3.2 and IV.3.3 are detailed. The results have been obtained with $k$-fold cross-validation, with $k=5$. Thus, for each combination of configuration and position, all 5 confusion matrixed are reported.

## Confusion matrixes for 5 classes on the PAMAP2 dataset

In this paragraph, the confusion matrixes obtained when testing the HBN model to classify 5 activities for the PAMAP2 dataset are reported. In the following, the list of the human activities used in this paragraph is specified:

1. stationary
2. walking
3. running
4. cycling
5. rope jumping

## Conf 1-3D accelerometer (with pre-processing)

Position: ankle16g

| Actual <br> class | Predicted class |  |  |  |  |

## Confusion matrixes for $\mathbf{1 2}$ classes on the PAMAP2 dataset

In this paragraph, the confusion matrixes obtained when testing the HBN model to classify all 12 standard activities for the PAMAP2 dataset are reported. In the following, the list of the human activities used in this paragraph is specified:

1. lying
2. sitting
3. standing
4. walking
5. running
6. cycling
7. Nordic walking
8. ascending stairs
9. descending stairs
10. vacuum cleaning
11. ironing
12. rope jumping

## Conf 2-3D accelerometer (no pre-processing)

## Position: ankle16g

## Confusion matrixes for $\mathbf{5}$ classes on the SHL dataset

In this paragraph, the confusion matrixes obtained when testing the HBN model to classify 5 activities for the SHL dataset are reported. In the following, the list of the activities used in this paragraph is specified:

1. still
2. walk
3. run
4. bike
5. car

## Confusion matrixes for 8 classes on the SHL dataset

In this paragraph, the confusion matrixes obtained when testing the HBN model to classify 5 activities for the SHL dataset are reported. In the following, the list of the activities used in this paragraph is specified:

1. still
2. walk
3. run
4. bike
5. car
6. bus
7. train
8. subway

## Conf 1-3D accelerometer (with pre-processing)

## Position: Bag

## Ringraziamenti

A conclusione di questo percorso vorrei dedicare un pensiero a tutte le persone che in qualche modo mi sono state vicino e mi hanno sostenuto. Questa tesi probabilmente non sarebbe altrimenti potuta esistere.

Ringrazio Romina, la persona che più di tutte mi ha accompagnato in questi ultimi tre anni (sappiamo che sono di più), con cui ho condiviso non solo le gioie ma anche le incertezze, le paure e, talvolta, lo sconforto che spesso hanno minato questo intenso percorso ormai volto al termine. Grazie per aver cacciato sempre via quei momenti.

Ringrazio i miei genitori, che nemmeno per un istante hanno dubitato di me e sempre hanno sostenuto e incoraggiato le mie scelte. Grazie per avermi trasmesso tutti i vostri valori, che ora formano anche il mio modo di essere uomo.

Ringrazio i miei amici-fratelli Aldo, Antonio, Francesco, Gerardo, Giovanni, Mattia. Grazie per tutte le risate e i momenti felici passati assieme.

Ringrazio l'allegra compagnia dell'aula studio: Carmine, Gio, Guido, Leo, Peppe, Rapesta, Simone. Anche se negli ultimi tre anni mi sono trasferito di un piano, lo spirito dell'how we made è sempre rimasto con me.

Ringrazio il prof. Licciardo, che prima di tutti ha puntato su di me e che ha reso possibile non solo la mia crescita professionale, ma anche umana.

Ringrazio Danilo che, insieme al prof. Licciardo, è stato mia guida e mentore a partire dai miei primi passi nel percorso di dottorato. Grazie per aver fatto restare sempre accesa in me la passione per la ricerca.

Ringrazio tutti quelli che più o meno stabilmente hanno condiviso con me le ore di lavoro al laboratorio di Microelettronica.

Ringrazio tutte le persone che ho incontrato al TIMA di Grenoble, in particolare Frédéric ed Olivier. Grazie per avermi guidato in quei mesi e per avermi dato nuovi spunti di riflessione. Ringrazio anche Breytner e Bruno per avermi accolto al TIMA non solo come collega ma anche come amico.

Ringrazio infine tutti i dottorandi del Dipartimento di Ingegneria Industriale con cui ho condiviso quest'esperienza, insieme ai docenti che ci hanno assistito.

## Acknowledgements

At the end of this path, I would like to give a thought to all the people who have always been there to support me. Probably, this thesis could not have come into existence without them.

Thank you to Romina, who more than anyone else has accompanied me throughout the last three years (more than three to be honest). With her I shared not only the joys, but also the uncertainties, the fears, and sometimes the discouragement, which have often undermined the intensive journey that has reached its conclusion now. Thanks for always having thrown away those moments-

Thank you to my parents, who never doubted me, not even for a moment, and always supported and encouraged my choices. Thanks for having conveyed to me your values, which have shaped my way to be a man.

Thank you to my friends-brothers Aldo, Antonio, Francesco, Gerardo, Giovanni, Mattia. Thanks for all the laughter and the happy moments we shared.

Thank you to the "aula studio" company: Carmine, Gio, Guido, Leo, Peppe, Rapesta, Simone. Even though I moved downstairs, the how we made spirit has always been with me.

Thank you to prof. Licciardo, who before all has bet on me and has made it possible not only my professional growth, but also my growth from a human perspective.

Thank you to Danilo, who has been a guide and a mentor starting from my first steps in the Ph.D. adventure. Thanks for keeping alive in me the passion for the scientific research.

Thank you to all those who more or less permanently have shared with me many working hours at the Microelettronica laboratory.

Thank you to all the people who I met at TIMA, in Grenoble, in particular Frédéric and Olivier. Thanks for having guided me in those months and for having given me many new insights. I also would like to thank Breytner and Bruno for having welcome me at TIMA, not only as a colleague but as friend as well.

Finally, I would like to say thank you to all the Ph.D. students at the Dipartimento di Ingegneria Industriale, together with all the professors who always assisted us.
